---

**Abstract**

We consider the transfer of verification techniques to structures with binding.

*Keywords:* games, typed lambda calculus, higher-order matching, higher-order schemes.

---

## 1 Introduction

A notable success in Computer Science has been the development of techniques for the computer-assisted verification of finite and infinite-state systems. These methods include model checking and equivalence checking. A general research goal is to transfer them to classes of finite and infinite-state systems with binding. In this paper we examine two problems involving typed  $\lambda$ -calculi, *higher-order matching* and *higher-order program schemes*.

The basic idea for understanding both these problems is to view typed  $\lambda$ -terms as *models* with binding, akin to transition graphs, and to understand their dynamical behaviour ( $\beta$ -reduction) by playing games on them without changing them using substitution. In the case of matching we assume we are given a potential solution term  $t$ . The model-checking game for  $t$  decides whether it is a solution. To transform this into a decision procedure for matching, one needs to find play uniformities that imply the small model property: if a problem has a solution then it has a small solution [26]. Here, we present the proof for the third-order case, as the small model property follows immediately from the tree-model property that every play descends a branch of a solution term. In the case of a scheme, we adopt Ong's presentation as an infinite term (that can be wrapped into a finite graph) [17]. We

<sup>1</sup> Email: [cps@inf.ed.ac.uk](mailto:cps@inf.ed.ac.uk)

define a scheme model checking game similar in spirit to game semantics as defined by Ong [17] but based on the ideas introduced for defining matching games.

In Section 2 we introduce higher-order matching and its equivalent problem, dual interpolation. The matching game is defined in Section 3 and in Section 4 we show decidability for the 3rd-order case. Higher-order schemes are introduced in Section 5 and their games in Section 6.

## 2 Matching and dual interpolation

We consider simple types that are generated from a single base type  $\mathbf{0}$  using the binary  $\rightarrow$  operator. A type is  $\mathbf{0}$  or  $A \rightarrow B$  where  $A$  and  $B$  are types. If  $A \neq \mathbf{0}$  then it has the form  $A_1 \rightarrow \dots \rightarrow A_n \rightarrow \mathbf{0}$ , assuming  $\rightarrow$  associates to the right, which is here written  $(A_1, \dots, A_n, \mathbf{0})$  following Ong [17]. A standard definition of *order* is: the order of  $\mathbf{0}$  is 1 and the order of  $(A_1, \dots, A_n, \mathbf{0})$  is  $k + 1$  where  $k$  is the maximum of the orders of the  $A_i$ s.

Terms of the simply typed  $\lambda$ -calculus are built from a countable set of typed variables  $x, y, \dots$  and typed constants  $a, f, \dots$  (each variable and constant has a unique type). The set of simply typed terms is the smallest set  $T$  such that

- (i) if  $x (f)$  has type  $A$  then  $x : A \in T (f : A \in T)$ ,
- (ii) if  $t : B \in T$  and  $x : A \in T$  then  $\lambda x.t : A \rightarrow B \in T$ ,
- (iii) if  $t : A \rightarrow B \in T$  and  $u : A \in T$  then  $tu : B \in T$ .

The *order* of a typed term is the order of its type. A typed term is *closed* if it does not contain free variables. Throughout, we assume the definitions of  $\alpha$ -equivalence,  $\beta$  and  $\eta$ -reduction.

**Definition 2.1** A *matching problem* is an equation  $v = u$  where  $v, u : \mathbf{0}$  and  $u$  is closed. The *order* of the problem is the maximum of the orders of the free variables  $x_1, \dots, x_n$  in  $v$ . A *solution* is a sequence of terms  $t_1, \dots, t_n$  such that  $v\{t_1/x_1, \dots, t_n/x_n\} =_{\beta\eta} u$ .

The decision question is: given a matching problem, does it have a solution? Matching is a particular instance of higher-order unification when the term  $u$  is closed: can  $v$  be pattern matched to  $u$ ? Although higher-order unification is undecidable (even if free variables are only second-order), higher-order matching was conjectured to be decidable by Huet [12]. If matching is decidable then it is known to have non-elementary complexity. Decidability has been proved for the general problem up to order 4 using observational equivalence of  $\lambda$ -terms and for various special cases [18,19]. Comon and Jurski define tree automata that characterize all solutions to a 4th-order problem, thereby, showing that they form a regular set [6]. Loader showed that matching is undecidable for the variant definition when  $\beta$ -equality is the same normal form by encoding  $\lambda$ -definability as matching [15], also see [13].

In [26], we describe a procedure that shows that matching is decidable that uses finite model checking games on  $\lambda$ -terms. In this paper, we describe the model checking game and how it leads to decidability for the third-order case, as a prelude

to examining (infinite) model checking games for higher-order schemes.

We assume that all terms in *normal form* are in  *$\eta$ -long form*,

- (i) if  $t : \mathbf{0}$  then it is  $u : \mathbf{0}$  where  $u$  is a constant or a variable, or  $u t_1 \dots t_k$  where  $u : (B_1, \dots, B_k, \mathbf{0})$  is a constant or a variable and each  $t_i : B_i$  is in  $\eta$ -long form,
- (ii) if  $t : (A_1, \dots, A_n, \mathbf{0})$  then  $t$  is  $\lambda y_1 \dots y_n. t'$  where each  $y_i : A_i$  and  $t' : \mathbf{0}$  is in  $\eta$ -long form.

Throughout we use  $\lambda z_1 \dots z_n$  for  $\lambda z_1 \dots \lambda z_n$ . A term is *well-named* if each occurrence of a variable  $y$  within a  $\lambda$ -abstraction is unique.

Assume  $u : \mathbf{0}$  and each  $v_i : A_i$ ,  $1 \leq i \leq n$ , is a closed term in normal form and  $x : (A_1, \dots, A_n, \mathbf{0})$ . An *interpolation equation* has the form  $x v_1 \dots v_n = u$  and an *interpolation disequation* is  $x v_1 \dots v_n \neq u$ . A finite family of interpolation equations  $x v_1^i \dots v_n^i = u_i$ ,  $i : 1 \leq i \leq m$ , with the same free variable  $x$  is an *interpolation problem*  $P$ . A finite family of interpolation equations and disequations,  $x v_1^i \dots v_n^i \approx_i u_i$ ,  $i : 1 \leq i \leq m$  and each  $\approx_i \in \{=, \neq\}$ , with the same free variable  $x$  is a *dual interpolation problem*  $P$ . The type of problem  $P$  is that of  $x$  and the order of  $P$  is the order of  $x$ . A *solution* of  $P$  of type  $A$  is a closed term  $t : A$  in normal form such that for each equation  $t v_1^i \dots v_n^i =_\beta u_i$  and for each disequation  $t v_1^i \dots v_n^i \neq_\beta u_i$ . We write  $t \models P$  if  $t$  is a solution of  $P$ .

Schubert shows that a matching problem of order  $n$  reduces to an interpolation problem of order at most  $n+2$  and Padovani shows it reduces to a dual interpolation problem of order  $n$  [20,19]. Because of normal forms,  $\beta$ -equality and  $\beta\eta$ -equality coincide. Consequently, the higher-order matching problem reduces to the following decision question: given a (dual) interpolation problem  $P$ , is there a term  $t \models P$ ?

**Example 2.2** The problem  $x \lambda y_1 y_2. y_1 \lambda y_3. f y_3 y_3 = f a a$  from [6] has order 3 with  $x : ((\mathbf{0}, \mathbf{0}), (\mathbf{0}, \mathbf{0}), \mathbf{0})$  and each  $y_i : \mathbf{0}$ .  $\square$

**Example 2.3** The problem  $x \lambda z. z = f(\lambda x_1 x_2 x_3. x_1(x_3))a$  also has order 3 where  $x$  has type  $((\mathbf{0}, \mathbf{0}), \mathbf{0})$ . This example illustrates that the closed term  $u : \mathbf{0}$  may contain bound variables: here  $f : (((\mathbf{0}, \mathbf{0}), \mathbf{0}, \mathbf{0}), \mathbf{0}, \mathbf{0})$ .  $\square$

### 3 Matching games

We use a game-theoretic characterization of dual interpolation inspired by model checking games (such as in [23]) where a model, a transition graph, is traversed relative to a property and players make choices at appropriate positions. Similarly, in the following game the model is a putative solution term  $t$  that is traversed relative to the dual interpolation problem  $P$ . The central motivation is to model the dynamics,  $\beta$ -reduction, without changing  $t$  by substituting into it. Because of binding play may jump around  $t$ .

A potential solution term  $t$  for  $P$  has the right type, is in normal form, is well-named (with variables that are disjoint from variables in  $P$ ). Term  $t$  is represented as a tree,  $\text{tree}(t)$ . If  $t$  is  $y : \mathbf{0}$  or  $a : \mathbf{0}$  then  $\text{tree}(t)$  is the single node labelled with  $t$ . In the case of  $u v_1 \dots v_k$  when  $u$  is a variable or a constant, we assume that a dummy

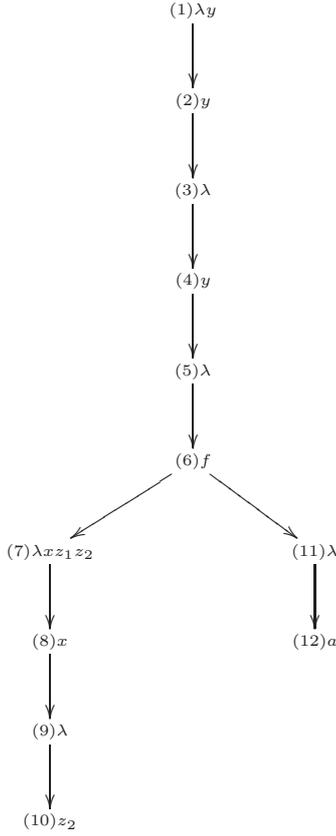

Fig. 1. A solution term

$\lambda$  with the empty sequence of variables is placed before any subterm  $v_i : \mathbf{0}$  in its tree representation. With this understanding, if  $t$  is  $uv_1 \dots v_k$  then  $\text{tree}(t)$  consists of the root node labelled  $u$  and  $k$ -successor nodes labelled with  $\text{tree}(v_i)$ . We use the notation  $u \downarrow_i t'$  to represent that tree  $t'$  is the  $i$ th successor of the node  $u$ . If  $t$  is  $\lambda\bar{y}.v$ , where  $\bar{y}$  is possibly empty, then  $\text{tree}(t)$  consists of the root node labelled  $\lambda\bar{y}$  and a single successor node  $\text{tree}(v)$ ,  $\lambda\bar{y} \downarrow_1 \text{tree}(v)$ .

In the following we use  $t$  to be the  $\lambda$ -term  $t$ , its  $\lambda$ -tree or the label (a constant, variable or  $\lambda\bar{y}$ ) at its root node.

**Example 3.1** A solution term  $t$  for the problem of Example 2.3 is  $\lambda y.y(y(f(\lambda x z_1 z_2.x(z_2)) a))$ . The tree for  $t$  (without indices on the edges) is in Figure 1. For instance, in this tree  $(6) \downarrow_2 (11)$ . There are various nodes in the tree with dummy  $\lambda$ s such as (5) and (9).  $\square$

We assume that each node of a tree  $t$  is uniquely identifiable: for instance, in Example 3.1 we labelled each node with a distinct natural number to distinguish different occurrences of  $z$  and  $\lambda$ .

Innocent game semantics following Ong in [17] provides a possible game-theoretic foundation. Given a potential solution term  $t$  and a (dis)equation  $xv_1^i \dots v_n^i \approx_i u_i$  there is the game board in Figure 2. Player Opponent chooses a branch of  $u_i$ .

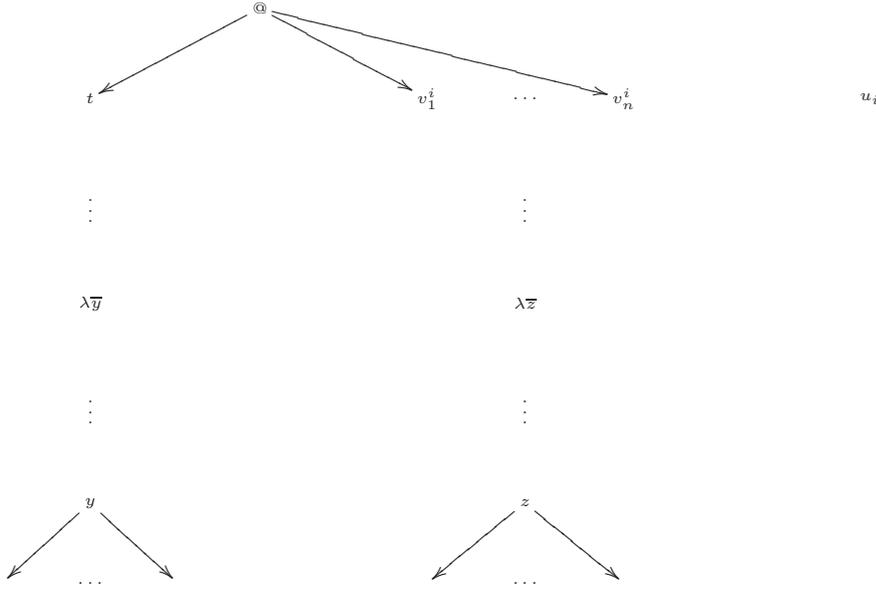

Fig. 2. Illustrating game semantics

Then, there is a finite play that starts at the root of  $t$  and may repeatedly jump in and out of  $t$  and in and out of the  $v_j^i$ 's. At a constant  $a : \mathbf{0}$  play ends. At other constants, player Proponent tries to match Opponent's choice of branch. Proponent wins, when the play finishes, if the sequence of constants encountered matches the branch chosen by Opponent. Play, for example, may reach  $y$  in  $t$  and then jump to  $\lambda\bar{z}$  in  $v_j^i$ , as it is the subtree at  $\lambda\bar{z}$  that is applied to  $\lambda\bar{y}$ , and then when at  $z$  in  $v_j^i$  play may return to  $t$  to an immediate successor of  $y$ . Game semantics models  $\beta$ -reduction on the fixed structure of Figure 2 without changing it using substitution. This is the rationale for the tree-checking game. However, it starts from the assumption that only  $t$  is the common structure for the problem  $P$ . So, play will always be in  $t$ . Jumping in and out of the  $v_j^i$ 's is coded using states, as play traverses  $t$ . Moreover, the game avoids the justification pointers of game semantics by appealing to iteratively defined look-up tables.

The tree-checking game  $G(t, P)$  is played by one participant, player  $\forall$ , the *refuter* who attempts to show that  $t$  is not a solution of  $P$ . It appeals to a finite set of states involving *left terms*, subterms of the  $v_j^i$ 's, and *right terms*, closed subterms of the  $u_i$ 's, of the matching (dis)equations in  $P$  (both modulo substitution of constants for bound variables that are directly below a constant  $f$ , as we shall see). There are three kinds of state: *argument*, *value* and *final* states. An argument state has the form  $q[(l_1, \dots, l_k), r]$  where each  $l_j$  is a left term (and  $k$  can be 0) and  $r$  is a right term. Such a state will occur at a node labelled  $\lambda z_1 \dots z_k$  in  $t$  where each  $l_j$  has the same type as  $z_j$ :  $(l_1, \dots, l_k)$  are the subterms applied to  $\lambda z_1 \dots z_k$ . A value state has the form  $q[l, r]$  where  $l$  is a left term and  $r$  a right term. This state is associated with a node labelled with a variable  $y$  in  $t$  where  $y$  and  $l$  share the same type:  $l$  is the subterm of some  $v_j^i$  that play at  $y$  would jump to in game semantics. A final state is either  $q[\forall]$  or  $q[\exists]$ .

- A.  $t_m = \lambda y_1 \dots y_j, t_m \downarrow_1 t'$  and  $q_m = q[(l_1, \dots, l_j), r]$ .  
 So,  $t_{m+1} = t', \theta_{m+1} = \theta_m\{l_1\eta_m/y_1, \dots, l_j\eta_m/y_j\}$  and  $q_{m+1}, \eta_{m+1}$  are defined by cases on  $t_{m+1}$ .
1.  $a : \mathbf{0}$ . So,  $\eta_{m+1} = \eta_m$ . If  $r = a$  then  $q_{m+1} = q[\exists]$  else  $q_{m+1} = q[\forall]$ .
  2.  $f : (B_1, \dots, B_k, \mathbf{0})$ . So,  $\eta_{m+1} = \eta_m$ . If  $r = fs_1 \dots s_k$  then  $q_{m+1} = q_m$  else  $q_{m+1} = q[\forall]$ .
  3.  $y : B$ . If  $\theta_{m+1}(y) = l\eta_i$ , then  $\eta_{m+1} = \eta_i$  and  $q_{m+1} = q[l, r]$ .
- B.  $t_m = f : (B_1, \dots, B_k, \mathbf{0}), t_m \downarrow_i t'_i$  and  $q_m = q[(l_1, \dots, l_j), fs_1 \dots s_k]$ .  
 So,  $\theta_{m+1} = \theta_m, \eta_{m+1} = \eta_m$  and  $\forall$  chooses a direction  $d : 1 \leq d \leq k$ .
1.  $t_{m+1} = t'_d$ . If  $s_d : \mathbf{0}$ , then  $q_{m+1} = q[(\ ), s_d]$ . If  $s_d$  is  $\lambda x_1 \dots x_n.s$  then  $q_{m+1} = q[(c_1, \dots, c_n), s\{c_1/x_1, \dots, c_n/x_n\}]$  where the  $c_i$ 's are new constants and each  $c_i$  has the same type as  $x_i$ .
- C.  $t_m = y$  and  $q_m = q[l, r]$ .  
 If  $l = \lambda z_1 \dots z_j.w$  and  $t_m \downarrow_i t'_i$  then  $\eta_{m+1} = \eta_m\{t'_1\theta_m/z_1, \dots, t'_j\theta_m/z_j\}$  else  $\eta_{m+1} = \eta_m$ . Elements  $t_{m+1}, q_{m+1}$  and  $\theta_{m+1}$  are by cases on  $l$ .
1.  $a : \mathbf{0}$  or  $\lambda \bar{z}.a$ . So,  $t_{m+1} = t_m$  and  $\theta_{m+1} = \theta_m$ . If  $r = a$  then  $q_{m+1} = q[\exists]$  else  $q_{m+1} = q[\forall]$ .
  2.  $c : (B_1, \dots, B_k, \mathbf{0})$ . So,  $\theta_{m+1} = \theta_m$ . If  $r \neq cs_1 \dots s_k$  then  $t_{m+1} = t_m$  and  $q_{m+1} = q[\forall]$ . Otherwise,  $\forall$  chooses a direction  $d : 1 \leq d \leq k$  and  $t'_{m+1} = t'$  where  $t'_m \downarrow_d t'$ . If  $s_d : \mathbf{0}$  then  $q_{m+1} = q[(\ ), s_d]$ . If  $s_d$  is  $\lambda x_1 \dots x_n.s$  then  $q_{m+1} = q[(c_1, \dots, c_n), s\{c_1/x_1, \dots, c_n/x_n\}]$  where the  $c_i$ 's are new constants and each  $c_i$  has the same type as  $x_i$ .
  3.  $fw_1 \dots w_k$  or  $\lambda \bar{z}.fw_1 \dots w_k$ . So,  $t_{m+1} = t_m$  and  $\theta_{m+1} = \theta_m$ . If  $r \neq fs_1 \dots s_k$  then  $q_{m+1} = q[\forall]$ . Otherwise,  $\forall$  chooses a direction  $d : 1 \leq d \leq k$ . If  $s_d : \mathbf{0}$  then  $q_{m+1} = q[w_d, s_d]$ . If  $s_d = \lambda x_1 \dots x_n.s$  and  $w_d = \lambda y_1 \dots y_n.w$  then  $q_{m+1} = q[w\{c_1/y_1, \dots, c_n/y_n\}, s\{c_1/x_1, \dots, c_n/x_n\}]$  where the  $c_i$ 's are new constants and each  $c_i$  has the same type as  $x_i$  and  $y_i$ .
  4.  $xl_1 \dots l_k$  or  $\lambda \bar{z}.xl_1 \dots l_k$ . If  $\eta_{m+1}(x) = t'\theta_i$  then  $t_{m+1} = t', \theta_{m+1} = \theta_i$  and  $q_{m+1} = q[(l_1, \dots, l_k), r]$ .

Fig. 3. Game moves

As play proceeds in  $t$ , there are two kinds of free variable: those in  $t$ , such as  $y$  in Figure 2, and those in the left terms of states, such as  $z$  in Figure 2. Free variables in  $t$  are associated with left terms and free variables in states are associated with nodes of  $t$ . So, the game appeals to a sequence of supplementary look-up tables  $\theta_k$  and  $\eta_k, k \geq 1$ :  $\theta_k$  is a partial map from variables in  $t$  to pairs  $l\eta_j$  where  $l$  is a left term and  $j < k$ , and  $\eta_k$  is a partial map from free variables in subterms of  $v_j^i$ , to pairs  $t'\theta_j$  where  $t'$  is a node of the tree  $t$  and  $j < k$ . A variable  $y$  in  $t$  may be associated with a left subterm  $l$  which contains free variables: hence, the need for  $\theta_k(y)$  to be a pair  $l\eta_j$  as  $\eta_j$  records the values of the free variables in  $l$  and  $j < k$ . Similarly, a variable in a left subterm may be associated with a subtree of  $t$  which contains free variables. Initially, at the beginning of play when there are no free variables,  $\theta_1$  and  $\eta_1$  are both empty.

(1) $q[(\lambda z.z), u]$	$\theta_1$	$\eta_1$		
(2) $q[\lambda z.z, u]$	$\theta_2$	$\eta_2$	$\theta_2 = \theta_1 \{(\lambda z.z)\eta_1/y\}$	$\eta_2 = \eta_1$ A3
(3) $q[(\ ), u]$	$\theta_3$	$\eta_3$	$\theta_3 = \theta_2$	$\eta_3 = \eta_2 \{(3)\theta_2/z\}$ C4
(4) $q[\lambda z.z, u]$	$\theta_4$	$\eta_4$	$\theta_4 = \theta_3$	$\eta_4 = \eta_1$ A3
(5) $q[(\ ), u]$	$\theta_5$	$\eta_5$	$\theta_5 = \theta_4$	$\eta_5 = \eta_4 \{(5)\theta_4/z\}$ C4
(6) $q[(\ ), u]$	$\theta_6$	$\eta_6$	$\theta_6 = \theta_5$	$\eta_6 = \eta_5$ A2

Fig. 4. Initial moves

A *play* of  $G(t, P)$  is a sequence of positions  $t_1 q_1 \theta_1 \eta_1, \dots, t_n q_n \theta_n \eta_n$  where each  $t_i$  is (the label of) a node of  $t$ ,  $t_1 = \lambda \bar{y}$  is the root node of  $t$ , each  $q_i$  is a state and  $q_n$  is a final state. A node  $t'$  of the tree  $t$  may repeatedly occur in a play. The initial state is decided as follows:  $\forall$  chooses a (dis)equation  $x(v_1^i, \dots, v_n^i) \approx_i u_i$  from  $P$  and  $q_1 = q[(v_1^i, \dots, v_n^i), u_i]$ . This is the same as an initial position in the game semantics, except the terms  $v_j^i$  and  $u_i$  are now part of the state (and the choice of branch in  $u_i$  takes place as play proceeds).

If the current position is  $t_m q_m \theta_m \eta_m$  and  $q_m$  is not a final state, then the next position  $t_{m+1} q_{m+1} \theta_{m+1} \eta_{m+1}$  is determined by a unique move in Figure 3. Moves are divided into three groups that depend on  $t_m$ . Group A covers the case when it is a  $\lambda \bar{y}$ , group B when it is a constant  $f$  (whose type is not  $\mathbf{0}$ ) and group C when it is a variable  $y$ . We assume standard updating notation for  $\theta_{m+1}$  and  $\eta_{m+1}$ :  $\beta\{\alpha_1/y_1, \dots, \alpha_m/y_m\}$  is the partial function similar to  $\beta$  except that  $\beta(y_i) = \alpha_i$ . In the case of rules B1, C2 and C3 we assume that the constants  $c_i$  are new: their role is to replace bound variables directly beneath a constant  $f$ . These are also the only rules where  $\forall$  can exercise choice, by carving out a branch. The look-up tables are used in rules A3 and C4 to interpret the two kinds of free variables. If  $t_m$  is a  $\lambda$  node,  $t_m \downarrow_1 t_{m+1}$  and  $t_{m+1}$  is the variable  $y$ , then  $\eta_{m+1}$  and  $q_{m+1}$  are determined by the entry for  $y$  in  $\theta_{m+1}$ : if it is  $l\eta_i$ , then  $l$  is the left element of  $q_{m+1}$  and  $\eta_{m+1} = \eta_i$ . In C4, if  $t_m = y$ ,  $q_m = q[l, r]$  and  $l = x(l_1, \dots, l_k)$  or  $\lambda \bar{z}.x(l_1, \dots, l_k)$ , then  $\theta_{m+1}$  and  $t_{m+1}$  are determined by the entry for  $x$  in the table  $\eta_{m+1}$ : if it is  $t'\theta_i$  then  $t_{m+1} = t'$  and  $\theta_{m+1} = \theta_i$ . It is this rule that allows play to jump elsewhere in the term tree (always to a node labelled with a  $\lambda$ ). In contrast, for A1-A3, B1 and C2 (unless play finishes) control passes down the term tree while it remains stationary in the case of C1 and C3.

A play of  $G(t, P)$  finishes with a final state  $q[\forall]$  or  $q[\exists]$ . Player  $\forall$  *wins* the play if the final state is  $q[\forall]$  and she *loses* it if the final state is  $q[\exists]$ .

**Example 3.2** Let  $P$  be the problem of Example 2.3 and let  $t$  be the term tree of Figure 1.  $G(t, p)$  consists of two plays that descend  $t$ . Both plays start as in Figure 4 where we have supplied which move is applied to produce the next position. The initial state is an argument state  $q[(\lambda z.z), u]$  and control is at node (1). Play descends from node (1) to (2) calling the value  $\lambda z.z$  by A3. Next, by C4, because  $z$  is the head variable in the body of  $\lambda z.z$ , has no arguments and is associated with node (3), the next state is the argument state  $q[(\ ), u]$  and control is at (3). Play descends from (3) to (4) calling the value  $\lambda z.z$  by A3. Again by C4,  $z$  is the head variable in the body of  $\lambda z.z$ , has no arguments and is now associated with (5), the next state is the argument state  $q[(\ ), u]$  and control is at (5). A2 is then applied

(because the right term  $u$  in the state has  $f$  as head constant) and control passes from (5) to (6). Move B1 is now applied and there is a  $\forall$  choice as to which branch of  $u$  to take. If direction 1 is chosen then play continues as follows.

(7) $q[(c_1, c_2, c_3), c_1(c_3)] \theta_7 \eta_7$	$\theta_7 = \theta_6$	$\eta_7 = \eta_6$	B1
(8) $q[c_1, c_1(c_3)] \theta_8 \eta_8$	$\theta_8 = \theta_7\{c_1\eta_7/x, c_3\eta_7/z_2\}$	$\eta_8 = \eta_7$	A3
(9) $q[(\ ), c_3] \theta_9 \eta_9$	$\theta_9 = \theta_8$	$\eta_9 = \eta_8$	C2
(10) $q[c_3, c_3] \theta_{10} \eta_{10}$	$\theta_{10} = \theta_9$	$\eta_{10} = \eta_7$	A3
(10) $q[\exists ] \theta_{11} \eta_{11}$	$\theta_{11} = \theta_{10}$	$\eta_{11} = \eta_{10}$	C1

New constants are introduced for replacing  $x_1, x_2, x_3$  in the body of  $u$  to give the right term  $c_1(c_3)$  and as arguments  $(c_1, c_2, c_3)$  for the variables  $x, z_1, z_2$  bound at (7). At (8) the value  $c_1$  is called and by C2, control proceeds to (9) where the right term is reduced to  $c_3$ . Finally, at (10), the value  $c_3$  is called, and by C1,  $\forall$  loses the play. She also loses if direction 2 is chosen.  $\square$

**Example 3.3** A solution to Example 2.2,  $xv_1v_2 = faa$ , is depicted in Figure 5 where  $v_1 = \lambda y_1 y_2 . y_1$  and  $v_2 = \lambda y_3 . f y_3 y_3$ . The moves are also shown. In fact there are two plays here: at position 4 there is a  $\forall$ -choice: however, both choices lead to the same position 5.  $\square$

If  $P$  is an interpolation problem then  $\forall$  loses the game  $G(t, P)$  if she loses every play: for each equation she loses every play whose initial state is from it. When  $P$  is a dual interpolation problem,  $\forall$  loses the game  $G(t, P)$  if for each equation she loses every play whose initial state is from it and if for each disequation she wins at least one play whose initial state is from it. The game characterizes dual interpolation and is proved in [25].

**Proposition 3.4**  $\forall$  loses  $G(t, P)$  if, and only if,  $t \models P$ .

The number of different plays in  $G(t, P)$  is bounded by the sum of the number of branches in the right terms  $u_i$  of  $P$ . We let  $\pi$  range over *subplays* that are consecutive subsequences of positions of any play of  $G(t, P)$ .

**Definition 3.5** The *length* of  $\pi$ ,  $|\pi|$ , is the number of positions in  $\pi$ . The  *$i$ th position* of  $\pi$ , for  $1 \leq i \leq |\pi|$ , is  $\pi(i)$  and  $\pi(i, j)$ ,  $i \leq j$ , is the *interval*  $\pi(i), \dots, \pi(j)$ .

For ease of notation, we write  $t \in \pi(i)$ ,  $q \in \pi(i)$ ,  $\theta \in \pi(i)$  and  $\eta \in \pi(i)$  if  $\pi(i) = tq\theta\eta$  and  $t \notin \pi(i)$  means that  $\pi(i) = t'q\theta\eta$  and  $t \neq t'$ . If  $q = q[(l_1, \dots, l_k), r]$  or  $q[l, r]$  then its *right term* is  $r$ .

**Definition 3.6** A subplay  $\pi$  is *ri, right term invariant*, if  $q \in \pi(1)$  and  $q' \in \pi(|\pi|)$  share the same right term  $r$ . It is *nri* if it is not ri and  $q' \in \pi(|\pi|)$  is not final.

**Definition 3.7** If  $\pi \in G(t, P)$  and  $\pi(i)$ 's look-up table is called when move A3 or C4 produces  $\pi(j)$ ,  $j > i$ , then position  $\pi(j)$  is a *child* of position  $\pi(i)$ . If  $\pi(i+1)$  is the result of move B1 or C2, then  $\pi(i+1)$  is a *child* of  $\pi(i)$ .

**Fact 3.8** If  $\pi \in G(t, P)$ ,  $j > 1$ ,  $\pi(j)$  is not a final position and  $\lambda \bar{y}$  or  $y \in \pi(j)$ , then there is a unique  $\pi(i)$ ,  $i < j$ , such that  $\pi(j)$  is a child of  $\pi(i)$ .

**Definition 3.9** A look-up table  $\beta'$  extends  $\beta$  if for all  $x \in \text{dom}(\beta)$ ,  $\beta'(x) = \beta(x)$ .

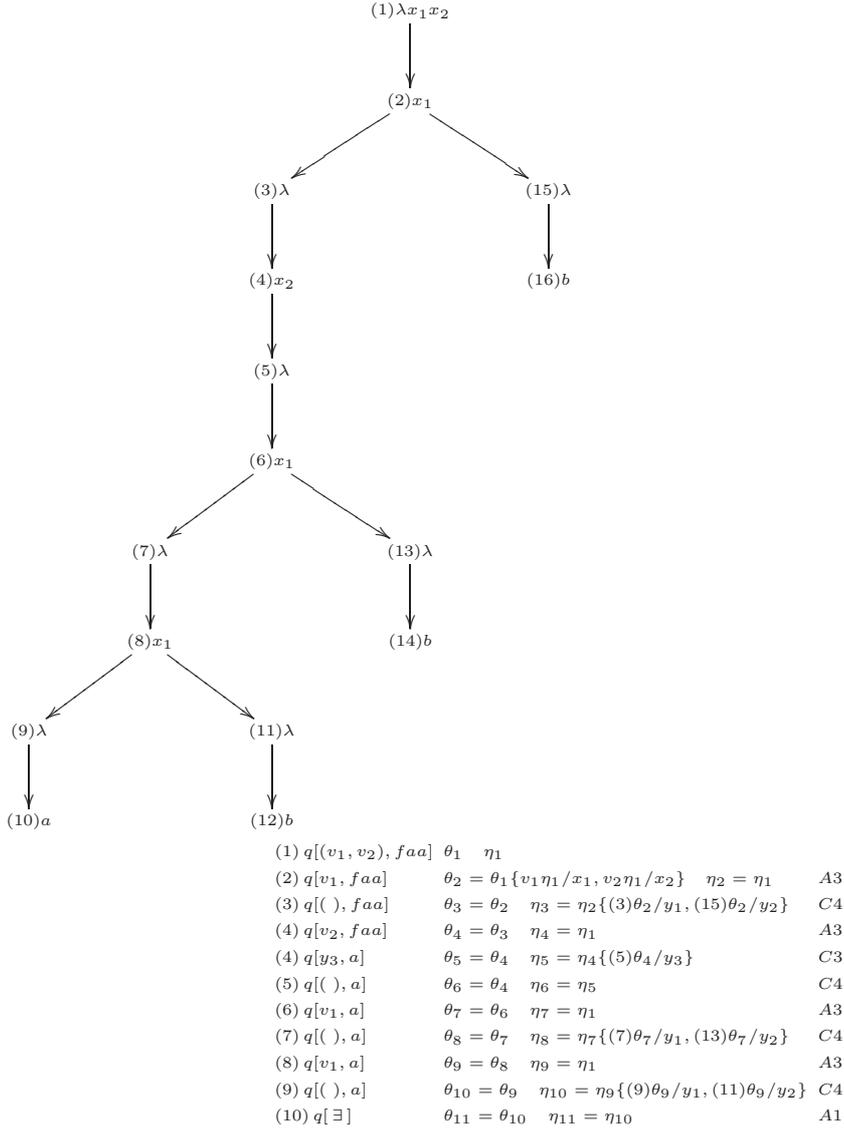

Fig. 5. Plays of a solution term to Example 2.2

**Fact 3.10** *If  $\pi(j)$  is a child of  $\pi(i)$  then  $\theta_j \in \pi(j)$  extends  $\theta_i \in \pi(i)$  and  $\eta_j \in \pi(j)$  extends  $\eta_i \in \pi(i)$ .*

## 4 Deciding third-order matching

We describe how the game-theoretic characterization of matching, Proposition 3.4, underpins decidability of third-order matching. The idea is to show the *small model property*: if  $t_0 \models P$  then there is a *small* term  $t' \models P$ . First, we relate the static structure of a solution tree  $t_0$  with the dynamics of playing.

**Definition 4.1** Assume  $B = (B_1, \dots, B_k, \mathbf{0})$ .

- (i)  $\lambda$  is an *atomic leaf* of type  $\mathbf{0}$ .
- (ii) If  $x_j : B_j$ ,  $1 \leq j \leq k$ , then  $\lambda x_1 \dots x_k$  is an *atomic leaf* of type  $B$ .
- (iii) If  $u : \mathbf{0}$  is a constant or variable then  $u$  is a *simple* tile.
- (iv) If  $u : B$  is a constant or a variable and  $t_j : B_j$ ,  $1 \leq j \leq k$ , are atomic leaves then  $u(t_1, \dots, t_k)$  is a *simple* tile.

The term tree  $t_0$  without its very top  $\lambda\bar{y}$  consists of simple tile occurrences. In Figure 5, nodes (2),(3) and (15) form the simple tile  $x_1(\lambda, \lambda)$  with atomic leaves  $\lambda$  and  $\lambda$ , (8), (9) and (11) form  $x_1(\lambda, \lambda)$ . Nodes such as (10) and (12) are also simple tiles without atomic leaves. The node (2) by itself or (2) with (3) are *not* simple tiles.

Throughout, our use of tile in  $t_0$  means “tile occurrence” in  $t_0$ . We write  $t(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  if  $t$  is a simple tile with atomic leaves  $\lambda\bar{x}_1, \dots, \lambda\bar{x}_k$ .

**Definition 4.2** Assume  $t$  and  $t'$  are simple tiles.

- (i)  $t'$  is *j-below*  $t(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  in  $t_0$  if there is a branch in  $t_0$  from  $\lambda\bar{x}_j$  to  $t'$ .
- (ii)  $t'$  is an *immediate j-dependent* of tile  $t$  in  $t_0$  if  $t'$  is *j-below*  $t$  and the head variable of  $t'$  is bound by a  $\lambda\bar{y}$  in  $t$ .
- (iii)  $t'$  is a *j-dependent* of  $t$  if it is an immediate *j-dependent* of  $t$  or there is a  $t''$  that is an immediate *j-dependent* of  $t$  and  $t'$  is a *j'-dependent* of  $t''$  for some  $j'$ .
- (iv)  $t'$  is a *dependent* of  $t$  if it is a *j-dependent* of  $t$  for some  $j$ .

In Figure 1, the tile  $x(\lambda)$  rooted at (8) is 1-below  $f(\lambda x z_1 z_2, \lambda)$  rooted at (6) and is, therefore, also an immediate 1-dependent of it

**Definition 4.3** Assume  $t = t(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  is a simple tile in  $t_0$ .

- (i)  $t$  is a *top* tile in  $t_0$  if its free variable  $y$  is bound by the initial lambda  $\lambda\bar{y}$  of  $t_0$ .
- (ii)  $t$  is *j-end* in  $t_0$ , if every free variable below  $\lambda\bar{x}_j$  in  $t_0$  is bound above  $t$ . It is an *end* tile in  $t_0$  if it is *j-end* for all  $j : 1 \leq j \leq k$ .
- (iii)  $t$  is a *constant* tile in  $t_0$  if its head is a constant or it is a dependent of a constant tile.

The tiles  $x_1(\lambda, \lambda)$  rooted at (2), (6) and (8) are top and end tiles in Figure 5. Tiles  $f(\lambda x z_1 z_2, \lambda)$  and  $x(\lambda)$  in Figure 1 are constant tiles.

Tiles can also be categorized in terms of their dynamic properties by appealing to *subplays* of  $\mathbf{G}(t_0, P)$ .

**Definition 4.4** A subplay  $\pi$  is a *play* on the simple tile  $u(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  in  $t_0$  if  $u \in \pi(1)$ ,  $\lambda\bar{x}_i \in \pi(|\pi|)$  for some  $i$  and  $\pi(|\pi|)$  is a child of  $\pi(1)$ . It is a *j-play* if  $\lambda\bar{x}_j \in \pi(|\pi|)$ .

A play on a simple constant tile  $u(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  is a pair of positions  $\pi(i, i+1)$  with  $u \in \pi(i)$  and  $\lambda\bar{x}_j \in \pi(i+1)$  for some  $j$  (by moves B1 or C2 of Figure 3). If  $\pi$  is the play in Example 3.2, then  $\pi(6, 7)$  is a 1-play on  $f(\lambda x z_1 z_2, \lambda)$  of Figure 1.

**Fact 4.5** *If  $\pi$  is a play on a simple constant tile then  $|\pi| = 2$ .*

In the general higher-order matching case, a play  $\pi$  on a simple non-constant tile  $y(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  in  $t_0$  can be of arbitrary length. It starts at  $y$  and finishes at a leaf  $\lambda\bar{x}_j$ . In between, flow of control can be almost anywhere in  $t_0$  (including  $y$ ). However, because of paucity of binding, play is very restricted in the third-order case. In a play  $\pi \in \mathbf{G}(t_0, P)$ , it is not possible for there to be more than one subplay on a simple tile of  $t_0$ : in [26], it is shown that if  $\pi(i, m)$  and  $\pi(i, n)$ ,  $n > m$ , are plays on the simple tile  $y(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  and  $\lambda\bar{x}_j \in \pi(m)$  then there is a position  $\pi(m')$ ,  $m' < n$ , that is a child of  $\pi(m)$ . Therefore, the following is an immediate corollary because a top tile in a third-order term tree has no dependent tiles.

**Proposition 4.6** *If  $\pi \in \mathbf{G}(t_0, P)$ ,  $P$  is third-order and  $t$  is a simple tile in  $t_0$  then there is at most one subplay on  $t$  within  $\pi$ .*

Assume  $P$  is a 3rd-order problem and  $t_0 \models P$ . If we inspect  $t_0$  top-down, starting beneath the initial  $\lambda$ , then it is a tree of simple tiles: each is a constant or a top tile that is also an end tile. The tree in Figure 1 consists of two initial top tiles  $y(\lambda)$  that are also end tiles and the constant tiles  $f(\lambda x z_1 z_2, \lambda)$ ,  $x(\lambda)$ ,  $z_2$  and  $a$ . Assume that  $\Pi = \{\pi_1, \dots, \pi_p\}$  are the plays of  $\mathbf{G}(t_0, P)$ . We define a partition of each  $\pi \in \Pi$  in stages. At each stage  $n$  we examine a simple tile  $t_n$  in  $t_0$  and a position  $\pi(i_n)$  whose control is at the head of  $t_n$ . We formalize that the subplay  $\pi(i_n, j_n)$  is a play on  $t_n$  or  $j_n = |\pi|$ . With each  $\pi \in \Pi$  we associate a unique *colour*  $c(\pi)$ .

For stage 1, we identify the initial simple tile  $t_1 = u(\lambda\bar{x}_1, \dots, \lambda\bar{x}_k)$  in  $t_0$  which is a constant or top tile (and possibly  $k = 0$ ). We examine the play on  $t_1$ , if there is one, consisting of moves  $\pi(i_1, j_1)$  where  $i_1 = 2$ . If there is no play we let  $j_1 = |\pi|$ , so  $q \in \pi(j_1)$  is final, and for all  $i : i_1 \leq i \leq j_1$  it follows that  $u \in \pi(i)$ : so, control never reaches beyond this initial tile. Tile  $t_1$  is then *final* for  $\pi$  and we terminate at this stage. Otherwise, the play on  $t_1$  ends at one of its atomic leaves  $\lambda\bar{x}_j$  and  $t_2$  is the simple tile directly below  $\lambda\bar{x}_j$  in  $t_0$  and  $i_2 = j_1 + 1$ . If the play  $\pi(i_1, j_1)$  on  $t_1$  is nri then  $t_1$  is coloured  $c(\pi)$ . At stage  $n$ , for any subsequent simple tile  $t_n$  we assume that the play  $\pi(i_n, j_n)$  is the play on  $t_n$ , if there is one. If there is not a play then  $j_n = |\pi|$  and  $t_n$  is final for  $\pi$ . If  $\pi(i_n, j_n)$  is an nri play on  $t_n$  then  $t_n$  is coloured  $c(\pi)$ . In this way, the partition of  $\pi$  descends a branch of  $t_0$  until it reaches a final tile.

**Example 4.7** For the tree of Figure 1 and the play  $\pi$  of Example 3.2 there is the following partition of  $\pi$ .

$$\begin{array}{cccccc} y & \lambda & y & \lambda & f & \lambda x z_1 z_2 & x & \lambda & z_2 \\ \pi(2, 3) & \pi(4, 5) & \pi(6, 7) & & \pi(8, 9) & \pi(10, 10) & & & \end{array}$$

Tiles  $f(\lambda x z_1 z_2, \lambda)$  and  $x(\lambda)$  are coloured  $c(\pi)$  and  $z_2$  is final for  $\pi$ . For the other play  $\pi'$  in this example, there is a similar partition.

$$\begin{array}{cccc} y & \lambda & y & \lambda & f & \lambda & a \\ \pi'(2, 3) & \pi'(4, 5) & \pi'(6, 7) & \pi'(8, 8) & & & \end{array}$$

where only  $f(\lambda x z_1 z_2, \lambda)$  is coloured  $c(\pi')$  and the tile  $a$  is final for  $\pi'$ .  $\square$

Consider partitioning with respect to all plays  $\pi \in \Pi$ . We slightly abuse notation: if  $\pi$  and  $\pi'$  are two plays we let  $\pi(i_n, j_n), \pi'(i_n, j_n)$  be subplays at stage  $n$  of their partition even when these intervals have different ranges. Instead of a sequence of simple tiles there is a tree of simple tiles, as they all share the initial tile. We select three kinds of simple tile in the tree. Tile  $t$  is *coloured* if it has at least one colour and  $t$  is *final* if it is final for at least one play. Each play at stage 1 that ends at the same atomic leaf of  $t_1$  shares  $t_2$  at stage 2 and so on. Therefore, branching occurs at  $t_m$  at stage  $m$  if there are plays that ended at the same atomic leaves of  $t_k, k < m$ , and at stage  $m$  plays end at different atomic leaves of  $t_m$ : tile  $t_m$  is then a (play) *separator*. In Example 4.7,  $f(\lambda x z_1 z_2, \lambda)$  separates the plays. If a simple tile in  $t_0$  is coloured, final or a separator then it is *special*.

A simple tile in  $t_0$  with atomic leaves that is not special is superfluous. Either every play avoids it or every subplay that passes through it is ri and ends at the same atomic leaf  $\lambda \bar{x}_j$ . If every play avoids the simple tile  $u(\lambda \bar{x}_1, \dots, \lambda \bar{x}_k)$  then we can replace the subtree rooted at  $u$  in  $t_0$  with the simple constant tile  $b : \mathbf{0}$ . If every subplay that passes through  $u(\lambda \bar{x}_1, \dots, \lambda \bar{x}_k)$  is ri and ends at the same atomic leaf  $\lambda \bar{x}_j$  and  $t_j$  is the subtree beneath  $\lambda \bar{x}_j$  of  $t_0$ , then we can replace the subtree rooted at  $u$  in  $t_0$  by  $t_j$ . Clearly, both these transformations preserve solution trees. For instance, the two occurrences of  $y(\lambda)$  in Example 4.7 are both redundant: the tree in Figure 1 is transformed by moving node (6) directly beneath node (1). The only significant tiles with atomic leaves are special. However, the number of coloured and final tiles is bound by the sum of the depths of the right terms  $u_i$  and the number of separators is at most  $p - 1$  (where  $p$  is the number of plays). So, the small model property follows where  $s(P)$  is the appropriate measure.

**Fact 4.8** *If  $t_0$  is a smallest solution to third-order  $P$ , then  $|t_0| \leq s(P)$ .*

For Example 4.7 the term whose tree is in Figure 1 is reduced by partitioning to  $\lambda y.f(\lambda x z_1 z_2.x(z_2))a$ . Similarly, the term in Figure 5 is reduced to  $\lambda x_1 x_2.x_2(a)$ .

The decidability proof exploits a key feature of game playing on a potential solution term  $t_0$  for third-order  $P$ , the *tree-model* property: each play  $\pi \in \mathbf{G}(t_0, P)$  descends a branch of  $t_0$  until a final state is reached. Because there is only one *level* of simple non-constant tiles, so, they are both top and end, game playing is heavily constrained. With a 4th or 5th-order tree there are two levels of simple non-constant tiles: top tiles  $y(\lambda \bar{x}_1, \dots, \lambda \bar{x}_k)$  and end tiles  $z(\lambda \bar{z}_1, \dots, \lambda \bar{z}_l)$  where  $z$  is bound by a  $\lambda \bar{x}_j$ . The number of levels increases with order: at 8th or 9th-order there are four levels. As soon as there is more than one level, game playing may jump around the tree. To show decidability of matching for the general case, the argument is much more involved and appeals to unfolding which is analogous to unravelling in modal logic. Unfolding induces the tree-model property. The proof of decidability uses unfolding followed by selective refolding (the inverse of unfolding) and from their combinatorial properties the small model property holds, see [26]. Here, instead we wish to consider *infinite* games on *infinite*  $\lambda$ -terms.

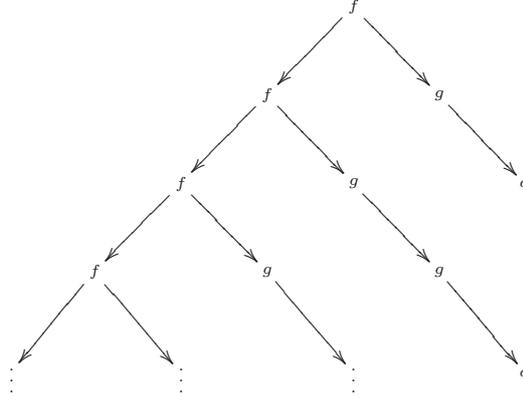

Fig. 6. The tree for Example 5.2

## 5 Higher-order program schemes

Assume  $\mathbf{0}$  is the domain of finite and infinite F-trees where each node is labelled by a basis function (constant)  $f \in F = \{f_1, \dots, f_k\}$ . Each  $f_i$  has an *arity* which is its degree of branching: if  $f_i : \mathbf{0}$  then it has arity 0 and  $f : (\mathbf{0}, \dots, \mathbf{0}, \mathbf{0})$  has arity the number of  $\mathbf{0}$ 's less one<sup>2</sup>. A higher-order program scheme, following Damm [8], is defined relative to a set of basis functions.

**Definition 5.1** A *scheme* is a finite family  $F_i x_1^i \dots x_{n_i}^i \stackrel{\text{def}}{=} t_i$ ,  $1 \leq i \leq m$ , of definitions where each  $F_i$  is typed and distinct, and each  $t_i : \mathbf{0}$  is built from the typed variables,  $x_1^i, \dots, x_{n_i}^i$ , basis functions and the  $F_i$ 's using application. There is also a start configuration  $S : \mathbf{0}$  without free variables built from the basis functions and  $F_i$ 's using application. The *order* of a scheme is the highest order of a variable  $x_j^i$  that occurs on the left hand side of a definition<sup>3</sup>.

**Example 5.2**  $Fx \stackrel{\text{def}}{=} fF(g(x))g(x)$  with start configuration  $Fa$  is first-order as  $x : \mathbf{0}$ : here,  $a$  has arity 0,  $g$  arity 1 and  $f$  arity 2.  $\square$

**Example 5.3** The following with start configuration  $Fgha$  is second-order.

$$\begin{aligned} Fx_1x_2x_3 &\stackrel{\text{def}}{=} f(F(Gx_1)(Hx_2)x_3)x_1(x_2(x_3)) \\ Gx_1x_2 &\stackrel{\text{def}}{=} g(y_1(y_2)) \\ Hx_1x_2 &\stackrel{\text{def}}{=} h(z_1(z_2)) \end{aligned}$$

Variables  $x_1, x_2, y_1, z_1 : (\mathbf{0}, \mathbf{0})$ ,  $x_3, y_2, z_2 : \mathbf{0}$ , constant  $a$  has arity 0,  $g, h$  arity 1 and  $f$  arity 2.  $\square$

A scheme is an abstracted functional program whose interpretation is the F-tree generated by  $S$ . For instance,  $Fa$  of Example 5.2 becomes  $fF(ga)ga$ , then  $f(fF(g(g(a)))g(g(a)))g(a)$  and so on, thereby generating the infinite tree whose

<sup>2</sup> The domain ordering is:  $\perp \sqsubseteq \mathbf{t}$  and  $\mathbf{t}_j \sqsubseteq \mathbf{t}'_j$  for each  $j$  implies  $f_i \mathbf{t}_1 \dots \mathbf{t}_k \sqsubseteq f_i \mathbf{t}'_1 \dots \mathbf{t}'_k$ .

<sup>3</sup> The matching literature assumes  $\mathbf{0}$  is of order 1, following first-order logic, whereas the scheme literature assumes  $\mathbf{0}$  is of order 0 following  $\lambda$ -calculus literature. However, the definition of the order of a scheme is then the highest order of any  $F_i$  which coincides with the definition here when  $\mathbf{0}$  has order 1.

initial part is depicted in Figure 6. Operationally, the following transition rules generate the tree when applied to  $S$ .

- (i)  $F_i s_1 \dots s_{n_i} \longrightarrow t_i \{s_1/x_1^i, \dots, s_{n_i}/x_{n_i}^i\}$
- (ii) If  $s_j \longrightarrow s'_j$  for  $1 \leq j \leq k$  then  $f_i s_1 \dots s_k \longrightarrow f_i s'_1 \dots s'_k$
- (iii) If  $a : \mathbf{0}$  then  $a \longrightarrow a$

Denotationally, the meaning of a scheme is the least fixed point with respect to the free interpretation of basis functions, following Damm [8]. For Example 5.2,  $F^0 a = \perp$  and  $F^{i+1} a = f(F^i(ga))ga$ . So  $F^2(a) = f(f(\perp)g(g(a)))g(a)$ . The resulting F-tree is  $F^\omega(a) = \bigsqcup_{i \geq 0} F^i(a)$  which is the meaning of  $Y(\lambda F. \lambda x. f(F(gx))g(x))a$ . Clearly, operational and denotational views coincide exactly. In the following we restrict attention to schemes that do not generate F-trees with undefined subtrees.

The definition of scheme, Definition 5.1, is slightly more generous than Damm's for order greater than 1. Damm's definition coincides with the *safe* schemes introduced by Knapik, Niwiński and Urzyczyn [14]: see [1,10] for a detailed discussion of this restriction and the proof that it indeed coincides with Damm's. An open question is whether safety restricts expressive power.

The classical *higher-order scheme problem* is: given two (possibly safe) schemes do they generate the same F-tree? One approach to understand this problem is to relate schemes to formal languages. Each basis function  $f \in F$  with arity  $n > 1$  can be split into terminal symbols  $f^1, \dots, f^n$  reflecting the different directions that can be taken. The *branch language* for an F-tree is the deterministic set of words which are paths from the root to a terminal node  $a : \mathbf{0}$ : for Figure 6,  $f^1 f^2 g g a$  is such a word. Courcelle showed that the equivalence problem for first-order schemes is interreducible to the equivalence checking problem for deterministic pushdown automata [7]. This problem was subsequently positively solved by Sénizergues [21,22,24]. For  $n > 1$ , equivalence of *safe*  $n$ th-order recursion schemes coincides with equivalence between deterministic  $n$ th-order pushdown automata [9,14].

Indeed, an open question is whether the branch language of an F-tree generated by a higher-order scheme is (deterministic) context-sensitive. For a first-order scheme, Courcelle shows it is a deterministic context-free language. Figure 8 illustrates that expressive power reaches beyond the context-free for schemes of order more than one. The family of languages recognized by second-order pushdown automata is the *indexed languages*, introduced by Aho in 1968 [2,3], which permit some context-dependency. Aho offers a grammatical method for generating them as well as an automata theoretic method (using nested stack automata) which turns out to be equivalent to the second-order pushdown automata, as shown by Maslov [16] who also defined a hierarchy of higher-order indexed languages characterized by higher-order pushdown automata, [16]. A more detailed account is given by Damm and Goerdt [9]. Aho also shows that the indexed languages are context-sensitive. They form an AFL and are a proper subset of the context-sensitive languages. It therefore follows that the branch languages of the F-trees generated by second-order *safe* schemes are deterministic context-sensitive. Aelig, de Miranda and Ong show that the branch language for an arbitrary second-order scheme is context-

2. Insert formal apply symbols  $@_A$ . Replace each ground type subterm of  $t$  and  $S$  of the form  $F_i e_1 \dots e_n$  where  $F_i : A = ((A_1, \dots, A_n, \mathbf{0}), A_1, \dots, A_n, \mathbf{0})$  by  $@_A F_i e_1 \dots e_n$ .
3. Lambda abstract the definition. If  $F x_1 \dots x_n \stackrel{\text{def}}{=} t'$  after stage 2 and  $n > 0$ , then replace it with  $F \stackrel{\text{def}}{=} \lambda x_1 \dots x_n. t'$ .
4. Rename bound variables so the set of equations and the start configuration are well named with respect to each other.

Wherever possible we omit the type  $A$  from  $@$ .

**Example 6.1** Stage 1 does not apply to Example 5.2. For stage 2, the start configuration becomes  $@Fa$  and the single equation becomes  $Fx \stackrel{\text{def}}{=} f(@F(g(x)))g(x)$ . After  $\lambda$ -abstraction,  $F \stackrel{\text{def}}{=} \lambda x. f(@Fg(x))g(x)$ .  $\square$

**Example 6.2** Example 5.3 is transformed into  $@F(\lambda u. g(u))(\lambda w. h(w))a$  as start configuration, where the constants  $g$  and  $h$  are  $\eta$ -expanded, with the following equations.

$$\begin{aligned} F &\stackrel{\text{def}}{=} \lambda x_1 x_2 x_3. f(@F(\lambda x. @G(\lambda v. x_1(v))x)(\lambda y. @H(\lambda s. x_2(s))y)x_3)(x_1(x_2(x_3))) \\ G &\stackrel{\text{def}}{=} \lambda y_1 y_2. g(y_1(y_2)) \\ H &\stackrel{\text{def}}{=} \lambda z_1 z_2. h(z_1(z_2)) \end{aligned}$$

In the first equation, the operand subterms  $Gx_1$  and  $Hx_2$  are  $\eta$ -expanded.  $\square$

This reformulation does not affect the tree generated using  $\beta$ -reduction and replacement of the  $F_i$ 's by their definitions: for instance  $@Fa = @(\lambda x. f(@Fg(x))(g(x)))a$  which  $\beta$ -reduces to  $f(@Fg(a))(g(a))$  assuming the standard interpretation of  $@$ .

The next step is to represent a scheme as a tree with backedges by systematically replacing all the  $F_i$ 's with their definitions. The idea is a simple generalization of the representation of terms in Section 3. First, we treat  $@_A$  when  $A = ((A_1, \dots, A_n, \mathbf{0}), A_1, \dots, A_n, \mathbf{0})$  as a constant with arity  $n + 1$ . To represent  $uv_1 \dots v_k$  when  $u$  is a variable or a constant (which now includes  $@$ ), we assume that a dummy  $\lambda$  with the empty sequence of variables is placed before any subterm  $v_i : \mathbf{0}$ . Moreover, any  $F_i$  is replaced with its definition. We use the notation  $u \downarrow_i t'$  to represent that tree  $t'$  is the  $i$ th successor of the node  $u$  as in Section 3.

For Example 6.1 we start with the initial term tree in Figure 8 where a dummy  $\lambda$  is introduced above  $a$ . This is then expanded to the second term tree in the figure, again with dummy  $\lambda$ 's. We could continue by replacing  $F$  with the subtree rooted at (2) and so on, to produce an infinite  $\lambda$ -term (which only contains finitely many variables). Instead, we assume that there is an edge from (5) to (2): that is (5)  $\downarrow_1$  (2). So the scheme produces a tree with backedges.

The aim is to understand the way a term generates an F-tree using games. Ong provides such a foundation using game semantics [17]. Again, to avoid justification pointers, the key is an appeal to iteratively defined look-up tables. However, the situation is simpler than for matching as there are only free variables in the tree.

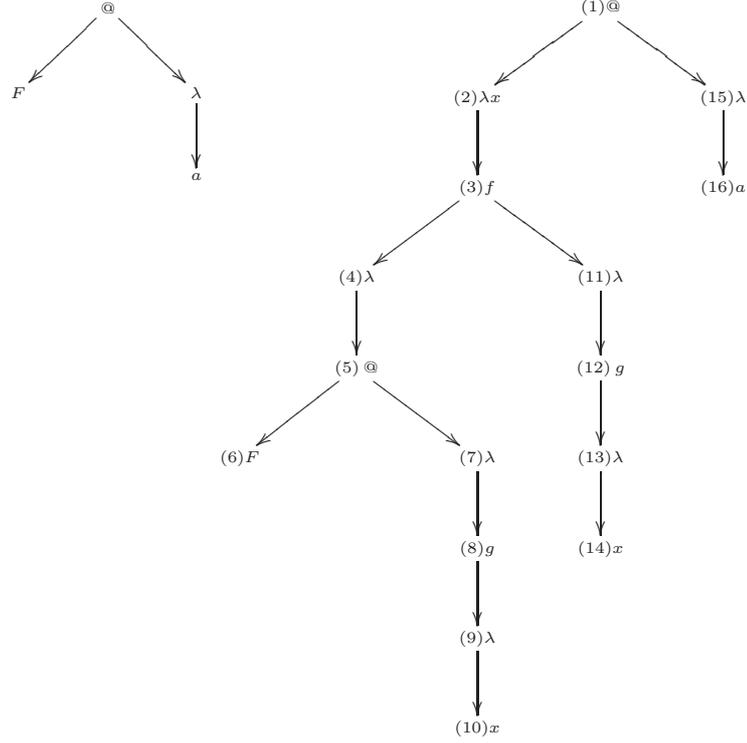

Fig. 8. The term tree for Example 6.1

- A.  $t_m = \lambda \bar{y}$  and  $t_m \downarrow_1 t'$ . Then  $t_{m+1} = t'$  and  $\theta_{m+1} = \theta_m$ .
- B.  $t_m = @_A$ ,  $A = ((A_1, \dots, A_n, \mathbf{0}), A_1, \dots, A_n, \mathbf{0})$ ,  $t_m \downarrow_i t'_i$  for  $1 \leq i \leq n+1$  and  $t'_1 = \lambda x_1 \dots x_n$ . Then  $t_{m+1} = t'_1$  and  $\theta_{m+1} = \theta_m \{t'_2 \theta_m / x_1, \dots, t'_{n+1} \theta_m / x_n\}$ .
- C.  $t_m = f$ ,  $f$  has arity  $n > 0$  and  $t_m \downarrow_i t'_i$  for  $1 \leq i \leq n$ . Then  $\forall$  chooses a direction  $j : 1 \leq j \leq n$  and  $t_{m+1} = t'_j$  and  $\theta_{m+1} = \theta_m$ .
- D.  $t_m = y : \mathbf{0}$  and  $\theta_m(y) = t' \theta_k$ . Then  $t_{m+1} = t'$  and  $\theta_{m+1} = \theta_k$ .
- E.  $t_m = y : (A_1, \dots, A_n, \mathbf{0})$ ,  $t_m \downarrow_i t'_i$  for  $1 \leq i \leq n$  and  $\theta_m(y) = t' \theta_k$  where  $t' = \lambda z_1 \dots z_n$ . Then  $t_{m+1} = t'$  and  $\theta_{m+1} = \theta_k \{t'_1 \theta_m / z_1, \dots, t'_n \theta_m / z_n\}$

Fig. 9. Game moves

We appeal to single look-up tables  $\theta_k$ :  $\theta_k$  is a partial map from variables in  $t$  to pairs  $t' \theta_j$  where  $t'$  is a node of the tree and  $j < k$ .

The basic game  $G(S)$  is played by one participant, player  $\forall$ . A *play* of  $G(S)$  is an infinite sequence of positions  $t_1 \theta_1, \dots$  or a finite sequence  $t_1 \theta_1, \dots, t_n \theta_n$  where  $t_n = a : \mathbf{0}$ . For the initial position,  $t_1$  is the root of the tree representation of  $S$  and  $\theta_1$  is  $\emptyset$ , the initial empty look-up table. If the current position is  $t_m \theta_m$  and  $t_m$  is not a constant  $a : \mathbf{0}$  then the next position  $t_{m+1} \theta_{m+1}$  is determined by a unique move in Figure 9. If play is at  $\lambda \bar{y}$  then it descends the tree. At  $@$ , play proceeds to the first successor  $\lambda x_1 \dots x_n$  and the look-up table is updated accordingly (the other successors  $t_{i+1}$  with the current look-up table is associated with  $x_i$ ). At a constant  $f$  with arity more than 0,  $\forall$  chooses a successor. If play is at a variable  $y : \mathbf{0}$  and the

entry in the current look-up table is  $t'\theta_k$  then play jumps to  $t'$  and  $\theta_k$  becomes the look-up table. If  $y$  is higher-order and its entry is  $t'\theta_k$  in the current look-up table  $\theta_m$  where  $t' = \lambda z_1 \dots z_n$  then play jumps to  $t'$  and the look-up table is  $\theta_k$  together with the association of  $t'_i\theta_m$  for each  $z_i$  when  $y \downarrow_i t'_i$ .

**Example 6.3** Consider  $G(S)$  when  $S$  is the tree in Figure 8. The first moves are as follows.

$$(1)\theta_1 \quad (2)\theta_2 = \theta_1\{(15)\theta_1/x\} \quad (3)\theta_2$$

At this point there is a  $\forall$ -choice. If play takes the right branch then play continues.

$$(11)\theta_2 \quad (12)\theta_2 \quad (13)\theta_2 \quad (14)\theta_2$$

Now  $x$  is called:  $\theta_2(x) = (15)\theta_1$ . So play continues with a jump:  $(15)\theta_1$  and ends at  $(16)\theta_1$ . The branch associated with this play is  $f^2ga$ . If the other choice is taken at position (3) then it continues.

$$(4)\theta_2 \quad (5)\theta_2 \quad (2)\theta_3 = \theta_2\{(7)\theta_2/x\} \quad (3)\theta_3$$

And again there is a  $\forall$ -choice. If the right branch is taken then play continues.

$$(11)\theta_3 \quad (12)\theta_3 \quad (13)\theta_3 \quad (14)\theta_3$$

Again  $x$  is called:  $\theta_3(x) = (7)\theta_2$ . So play now jumps to (7) and proceeds to (10) before jumping to (15) and finishing at (16): the branch associated with this play is  $f^1f^2gga$ . There is just one infinite play in  $G(S)$  when the left branch at (3) is always chosen.  $\square$

**Example 6.4** We now examine plays of  $G(S)$  for  $S$  in Figure 10. Play starts as follows.

$$(1)\theta_1 \quad (2)\theta_2 = \theta_1\{(42)\theta_1/x_1, (46)\theta_1/x_2, (50)\theta_1/x_3\} \quad (3)\theta_2$$

If  $\forall$  chooses the right branch of  $f$  then play continues.

$$(36)\theta_2 \quad (37)\theta_2 \quad (42)\theta_3 = \theta_1\{(38)\theta_2/u\}$$

Because  $\theta_2(x_1) = (42)\theta_1$ , when play jumps to (42) the look-up table associates  $(38)\theta_2$  with  $u$ . Play proceeds to (45) and returns to (38).

$$(43)\theta_3 \quad (44)\theta_3 \quad (45)\theta_3 \quad (38)\theta_2 \quad (39)\theta_2$$

Now it jumps to (46)

$$(46)\theta_4 = \theta_1\{(40)\theta_2/w\} \quad (47)\theta_4 \quad (48)\theta_4 \quad (49)\theta_4$$

and returns to (40).

$$(40)\theta_2 \quad (41)\theta_2 \quad (50)\theta_1 \quad (51)\theta_1$$

The branch associated with this play is  $f^2gha$ .  $\square$

Given a scheme  $S$ , the F-tree generated from the game  $G(S)$  is the tree with internal nodes  $f$  and subtrees determined by  $\forall$ 's choice when position  $C$  of Figure 9 is encountered, and leaf nodes  $a$  when play finishes at this constant.

**Proposition 6.5** *The F-tree generated by  $S$  is the F-tree generated by  $G(S)$ .*

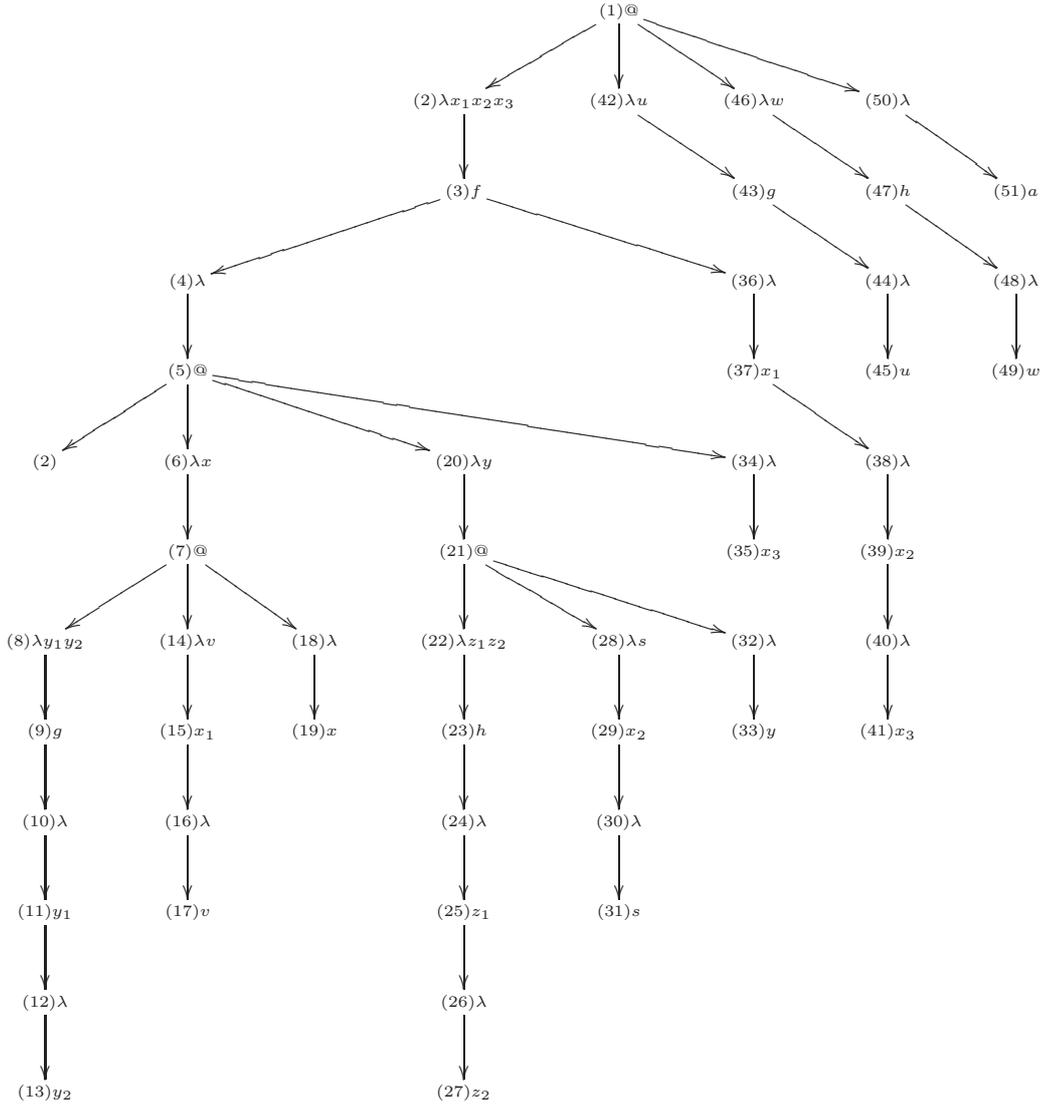

Fig. 10. The term tree for Example 6.2

**Proof.** We show that each prefix of the F-tree generated by  $S$  is the same prefix of the F-tree generated by  $G(S)$  and that the remaining subtrees are the same. To do this we show that the operational semantics of a scheme  $S$  that is expanded into normal form when look-up tables  $\theta_i$  are interpreted as delayed substitutions is isomorphic to game playing. Initially, the scheme operationally is  $S$  and the initial move in  $G(S)$  is  $S\theta_1$  where  $\theta_1$  is the empty look-up table: consequently the same. Assume current branch  $f_1^{i_1} \dots f_k^{i_k}$  in the prefix of the F-tree and  $t_m\theta_m$  is the current position in the play. We proceed by cases on  $t_m$ . If  $t_m = @$ , so  $@(\lambda x_1 \dots x_n.t')t_2 \dots t_{n+1}\theta_m$  is the current unfolding in the operational semantics: this generates the F-tree  $t'\theta_m\{t_2\theta_m/x_1, \dots, t_{n+1}\theta_m\}$ . Game theoretically, play first goes to the node labelled  $\lambda x_1 \dots x_n$  with  $\theta_{m+1} = \theta_m\{t_2\theta_m/x_1, \dots, t_{n+1}\theta_m\}$  and then play goes to  $t'\theta_{m+1}$ , as required. If  $t_m = f$  and so  $ft_1 \dots t_n\theta_m$  is the current unfolding in the operational

semantics then the branch  $f_1^{i_1} \dots f_k^{i_k}$  is expanded with  $f^j$  for  $1 \leq j \leq n$ , and the  $j$ th subtree is  $t_j\theta_m$ . Clearly, in the game if  $\forall$  chooses direction  $j$  then the next position is  $t_j\theta_m$ . If  $f : \mathbf{0}$  then it is a leaf of the F-tree and  $t_m\theta_m$  is a final position in a play. If  $t_m = y$  and so  $yt_1 \dots t_n\theta_m$  is the current unfolding in the operational semantics then this generates the F-tree  $\theta_m(y)t_1\theta_m \dots t_n\theta_m$ : if  $\theta_m(y) = \lambda z_1 \dots z_n. t'\theta_k$  then this reduces to  $t'\theta_k\{t_1\theta_m/z_1, \dots, t_n\theta_m/z_n\}$  and the game follows suit. A similar argument holds for the case  $y : \mathbf{0}$ .  $\square$

The issue is whether the game-theoretic characterization of the F-tree generated by a scheme can underpin useful decision procedures. Ong [17], using game-semantics, shows how an alternating parity automaton that runs on the F-tree can be transformed into one that runs on the term tree. The idea is to include assumptions about play jumping with the descent of an automaton down a leftmost successor of  $\textcircled{!}$ : these assumptions are then checked by spawning auxiliary automata that descend the other successors of the  $\textcircled{!}$ . We can employ the tile classification of regions of the scheme tree, and their subplays as described for matching, as an alternative basis for this decidability proof. Much more work is needed to discover relationships between the static structure of a scheme and the dynamics of game playing.
