Dependency Grammar Induction
with a Neural Variational Transition-based Parser

Abstract
Dependency grammar induction is the task of learning dependency syntax without annotated training data. Traditional graph-based models with global inference achieve state-of-the-art results on this task but need $O(n^3)$ run time. Transition-based models achieve faster inference with $O(n)$ time complexity, but previous work on transition-based models using relatively simple features failed to match the performance of graph-based models. In this work, we propose a neural variational transition-based parser with sampling-based inference, which can utilize rich features while keeping $O(n)$ time complexity. We augment the parser with posterior regularization and variance reduction techniques. The resulting framework outperforms previous unsupervised transition-based dependency parsers and achieves performance comparable to graph-based models, both on the English Penn Treebank and on the Universal Dependency Treebank. In an empirical comparison, we show that our approach substantially increases parsing speed over graph-based models.

Introduction
Grammar induction is the task of deriving plausible syntactic structures from raw text, without the use of annotated training data. In the case of dependency parsing, the syntactic structure takes the form of a tree whose nodes are the words of the sentence, and whose arcs are directed and denote head-dependent relationships between words. Inducing such a tree without annotated training data is challenging because of data sparseness and ambiguity, and because the search space of potential trees is very large, making optimization difficult.

Most existing approaches to dependency grammar induction have used inference over graph structures and are based either on the dependency model with valence (DMV) of Klein and Manning (2004) or the maximum spanning tree algorithm (MST) for dependency parsing by McDonald, Petrov, and Hall (2011). State-of-the-art representatives include LC-DMV (Noji, Miyao, and Johnson, 2016) and Convex-MST (Grave and Elhadad, 2015). Recently, researchers have also introduced neural networks for feature extraction in graph-based models (Jiang, Han, and Tu, 2016; Cai, Jiang, and Tu, 2017).

Though graph-based models achieve impressive results, they suffer from the $O(n^3)$ time complexity of the global inference. To make global inference feasible, the features in graph-based models have to be restricted. Even discriminative graph-based models (Grave and Elhadad, 2015; Cai, Jiang, and Tu, 2017) can only access sequential features, while more powerful features like partial parse trees cannot be used. Transition-based models allow faster inference with linear time complexity; furthermore, thanks to a more flexible structure, transition-based models allow the use of much richer feature sets. Although not using global inference, transition-based models have been shown to perform well in supervised parsing (Kiperwasser and Goldberg, 2016; Dyer et al., 2015). Unsupervised transition-based models, in contrast, are much less well-studied. One exception is the work of Rasooli and Faili (2012), in which search-based structure prediction (Daumé III, 2009) is used with a simple feature set. However, there is still a large performance gap compared to graph-based models.

Recently, Dyer et al. (2016) proposed a recurrent neural network grammar (RNNG) framework, which is a probabilistic model of constituency trees. RNNG can be used either in a generative way as a language model or in a discriminative way as a parser, and the combination of discriminative and generative RNNGs achieves excellent performance in constituency parsing. Cheng, Lopez, and Lapata (2017) propose to use neural variational inference to integrate discriminative and generative RNNGs, yielding a reconstruction process with parse trees as latent variables which enables the two components to be trained jointly on a language modeling objective and achieve better performance. However, this method still focuses on using observed trees for training, lacking the ability to infer latent trees in an unsupervised fashion.

In this paper, we make a more radical departure from the existing literature in dependency grammar induction by proposing an unsupervised neural variational transition-based parser. Specifically, we first modify the transition actions in the original RNNG into a set of arc-standard actions for projective dependency parsing, and then build a dependency variant of the model of Cheng, Lopez, and Lapata (2017). Although this approach performs well for supervised parsing, when applied in unsupervised parsing, the performance decreases dramatically (see section Experiments...
for details). We hypothesize that this is because without prior linguistic knowledge, the parser is too unconstrained (Naseem et al., 2010; Noji, Miyao, and Johnson, 2016). Therefore, we augment the model with posterior regularization, allowing us to seamlessly integrate linguistic knowledge in the shape of a small number of universal linguistic rules. In addition, we propose a novel variance reduction method for stabilizing neural variational inference with discrete latent variables. This yields the first known model that makes it possible to use a rich feature set for unsupervised dependency parsing. When evaluating on the English Penn Treebank and on eight languages from the Universal Dependency (UD) Treebank, we find that our model with posterior regularization outperforms the best unsupervised transition-based dependency parser (Rasooli and Faili, 2012), and approaches the performance of graph-based models. We also show how a weak form of supervision can be integrated elegantly into our framework in the form of rule expectations. Finally, we present empirical evidence for the complexity advantage of transition-based models: our model attains a large speed-up compared to a state-of-the-art graph-based model. Code and Supplementary Material are available.1

Background

RNNG is a top-down transition system originally proposed for constituency parsing and generation. There are two variants: the discriminative RNNG and the generative RNNG. The discriminative RNNG takes a word sequence as input and outputs the probability of generating a corresponding parse tree. The model uses a buffer to store unprocessed terminal symbols and a stack to store partially completed syntactic constituents. It then follows top-down transition actions to shift words from the buffer to the stack to construct syntactic constituents incrementally.

The discriminative RNNG can be modified slightly to formulate the generative RNNG, an algorithm for simultaneously generating trees and sentences. In this variant, there is no buffer of unprocessed input words, but there is an output buffer for storing words that have been generated. Top-down actions are then specified to generate words and tree non-terminals in pre-order. Though not able to parse on its own, a generative RNNG can be used for language modeling as long as parse trees are sampled from a proper distribution.

We modify the transition actions in the original RNNG into a set of arc-standard actions for projective dependency parsing. In the discriminative modeling case, the action space includes:

- **SHIFT** fetches the first word in the buffer and pushes it onto the top of the stack.
- **LEFT-REDUCE** adds a left arc in between the top two words of the stack and merges them into a single construct.
- **RIGHT-REDUCE** adds a right arc in between the top two words of the stack and merges them into a single construct.

In the generative modeling case, the **SHIFT** operation is replaced by a **GEN** operation:

- **GEN** generates a word and adds it to the stack and the output buffer.

Methodology

To build our dependency grammar induction model, we first extend the encoder-decoder RNNG proposed by Cheng, Lopez, and Lapata (2017) to a dependency-based framework. This basic framework includes two dependency RNNG variants as well as a training scheme: (1) a discriminative RNNG as the encoder for mapping the input sentence into a latent variable, which for the grammar induction task is a sequence of parse actions for building the dependency tree; (2) a generative RNNG as the decoder for reconstructing the input sentence based on the latent parse actions; (3) the likelihood of the observed input sentence as the training objective, which is reformulated as an evidence lower bound (ELBO) in neural variational inference and is optimized with the REINFORCE algorithm (Miao, Yu, and Blunsom, 2016; Miao and Blunsom, 2016). In this manner, the encoder and decoder can be trained jointly, and learn the latent parse actions based only on the input text. To further regularize the space of induced parse trees and to incorporate a linguistic prior, we introduce posterior regularization into the basic framework. Lastly, we propose a novel variance reduction technique to train our posterior regularized framework more effectively.

Encoder

We formulate the encoder as a discriminative dependency RNNG that computes the conditional probability \( p(a|x) \) of the transition action sequence \( a \) given the observed sentence \( x \). The conditional probability is factorized over time steps:

\[
p(a|x) = \prod_{t=1}^{|a|} p(a_t|v_t) \tag{1}
\]

where \( v_t \) is the transitional state embedding of the encoder at time step \( t \).

Decoder

The decoder is a generative dependency RNNG that models the joint probability \( p(x,a) \) of a latent transition action sequence \( a \) and an observed sentence \( x \). This joint distribution can be factorized into a sequence of action and word (emitted by **GEN**) probabilities, which are parameterized by a transitional state embedding \( u \):

\[
p(x,a) = p(a)p(x|a) = \prod_{t=1}^{|a|} p(a_t|u_t)p(x_t|u_t) I(a_t=\text{GEN}) \tag{2}
\]

where \( I \) is an indicator function and \( u_t \) is the state embedding at time step \( t \). The features and the modeling details of both the encoder and the decoder can be found in the Supplementary Material.
Neural Variational Inference

Consider a latent variable model in which the encoder infers the latent transition actions (i.e., the dependency structure) and the decoder reconstructs the sentence from these actions. The maximum likelihood estimate of the model parameters is determined by the log marginal likelihood of the sentence:

$$\log p(x) = \log \sum_a p(x, a)$$

Since the form of the log likelihood is intractable in our case, we use neural variational inference techniques to construct the ELBO (by Jensen’s Inequality) as follows:

$$\log p(x) \geq \log p(x) - KL[q(a)||p(a|x)]$$

$$= \mathbb{E}_{q(a)}[\log \frac{p(x, a)}{q(a)}] = \mathcal{L}_x$$

where $KL$ is the Kullback-Leibler divergence and $q(a)$ is the variational approximation of the true posterior. The EM algorithm can be employed to optimize the loss function. In the E-step, we approximate the variational distribution $q(a)$ based on the encoder and the observation $x$ (i.e., parameterize $q(a)$ as $q_w(a|x)$). Similarly, the joint probability $p(x, a)$ can be parametrized by the decoder as $p_\theta(x, a)$.

In the M-step, the decoder parameters $\theta$ can be directly updated by gradient descent via Monte Carlo simulation:

$$\frac{\partial \mathcal{L}_x}{\partial \theta} = \mathbb{E}_{q_w(a|x)}[\frac{\partial \log p_\theta(x, a)}{\partial \theta}]$$

$$\approx \frac{1}{M} \sum_m \log p_\theta(x, a^{(m)})$$

where $M$ samples $a^{(m)} \sim q_w(a|x)$ are drawn independently to compute the stochastic gradient.

For the encoder parameters $\omega$, since the sampling operation is not differentiable, we approximate the gradients using the REINFORCE algorithm (Williams, 1992):

$$\frac{\partial \mathcal{L}_x}{\partial \omega} = \mathbb{E}_{q_w(a|x)}[l(x, a) \frac{\partial \log q_w(a|x)}{\partial \omega}]$$

$$\approx \frac{1}{M} \sum_m l(x, a^{(m)}) \frac{\partial \log q_w(a^{(m)}|x)}{\partial \omega}$$

where $l$ is the score function computed as:

$$l(x, a) = \log \frac{p_\theta(x, a)}{q_w(a|x)}$$

Posterior Regularization

As will become clear in the later sections, the basic model discussed previously performs poorly when used for unsupervised parsing, barely outperforming a left-branching baseline for English. We hypothesize that the basic model is too unconstrained: without any constraints to regularize the latent space, the induced parses will be arbitrary, since the model is only trained to maximize sentence likelihood (Naseem et al., 2010; Noji, Miyao, and Johnson, 2016).

We therefore introduce posterior regularization (PR; Ganchev et al., 2010) to encourage the neural network to generate well-formed trees. Via posterior regularization, we can give the model access to a small amount of linguistic information in the form of universal syntactic rules (Naseem et al., 2010), which are the same for all languages. These rules effectively function as features, which impose soft constraints on the neural parameters in the form of expectations.

To integrate the PR constraints into the model, a set $Q$ of allowed posterior distributions over the hidden variables $a$ can be defined as:

$$Q = \{ q(a) : \mathbb{E}_q[\phi(x, a)] - b \leq \xi : ||\xi||_\beta \leq \varepsilon \}$$

where $\phi(x, a)$ is a vector of feature functions, $b$ is a vector of given negative expectations, $\xi$ is a vector of slack variables, $\varepsilon$ is a predefined small value and $|| \cdot ||_\beta$ denotes some norm. The PR algorithm only works if $Q$ is non-empty.

In dependency grammar induction, $\phi_k(x, a)$ (the $k^{th}$ element in $\phi(x, a)$) can be set as the negative number of times a given rule (dependency arcs, e.g., Root $\rightarrow$ Verb, Verb $\rightarrow$ Noun) occurs in a sentence. We hope to bias the learning so that each sentence is parsed to contain these kinds of arcs more than a threshold in the expectation. The posterior regularized likelihood is then:

$$\mathcal{L}_Q = \max_{q \in Q} \mathcal{L}_x$$

$$= \log p(x) - \min_{q \in Q} KL[q(a)||p(a|x)]$$

Equation (9) indicates that, in the posterior regularized framework, $q(a)$ not only approximates the true posterior $p(a|x)$ (estimated by the encoder network $q_w(a|x)$) but also belongs to the constrained set $Q$. To optimize $\mathcal{L}_Q$ via the EM algorithm, we get the revised E’-step as:

$$q(a) = \arg\max_{q \in Q} \mathcal{L}_Q$$

$$= \arg\min_{q \in Q} KL[q(a)||q_w(a|x)]$$

Formally, the optimization problem in the E’-step can be described as:

$$\min_{q, \xi} KL[q(a)||q_w(a|x)]$$

s.t. $\mathbb{E}_q[\phi(x, a)] - b \leq \xi : ||\xi||_\beta \leq \varepsilon$

Following Ganchev et al., (2010), we can solve the optimization problem in (11) in its Lagrangian dual form. Since our transition-based encoder satisfies the decomposition property, the conditional probability $q_w(a|x)$ can be factored as $\prod_{a} q_w(a_t|v_t)$ in (1). Thus, the factored primal solution can be written as:

$$q(a) = \frac{q_w(a|x)}{Z(\lambda^*)} \exp(-\lambda^T \phi(x, a))$$

where $\lambda^*$ is the Lagrangian multiplier whose solution is given as $\lambda^* = \arg\max_{\lambda \geq 0} -\beta^T \lambda - \log Z(\lambda) - \varepsilon \cdot ||\lambda||_{\beta^2}$ and $Z(\lambda)$ is given as:

$$Z(\lambda) = \sum_a q_w(a|x) \exp(-\lambda^T \phi(x, a))$$

$2\cdot || \cdot ||_\beta^2$ is the dual norm of $|| \cdot ||_\beta$. Here we use $\ell_2$ norm for both primal norm $|| \cdot ||_\beta$ and dual norm $|| \cdot ||_\beta^2$. 

We also define the multiplier computed by PR as:
\[
\gamma(a, x) = \frac{1}{Z(\lambda)} \exp(-\lambda^T \phi(x, a)) \tag{14}
\]

In our case, computing the normalization term \(Z(\lambda)\) is intractable for transition-based dependency parsing systems. To address this problem, we view \(Z(\lambda)\) as an expectation and estimate it by Monte Carlo simulation as:
\[
Z(\lambda) = \mathbb{E}_{q_\theta(a|x)}[\exp(-\lambda^T \phi(x, a))] \\
\approx \frac{1}{M} \sum_{m} \exp(-\lambda^T \phi(x, a^{(m)})) \tag{15}
\]

Finally, we compute the gradients for encoder and decoder in the M-step as follows:
\[
\frac{\partial L_x}{\partial \theta} = \frac{1}{M} \sum_{m} \gamma(x, a^{(m)}) l(x, a^{(m)}) \frac{\partial \log p_\theta(x, a^{(m)})}{\partial \theta},
\]
\[
\frac{\partial L_x}{\partial \omega} = \frac{1}{M} \sum_{m} \gamma(x, a^{(m)}) l(x, a^{(m)}) \frac{\partial \log q(a^{(m)})}{\partial \omega} \tag{16}
\]

where \(l\) is the score function computed as in (7). Details of the derivation of the M-step can be found in the Supplementary Material.

**Variance Reduction in the M-step**

Training a neural variational inference framework with discrete latent variables is known to be a challenging problem (Mnih and Gregor, 2014; Miao and Blunsom, 2016; Miao, Yu, and Blunsom, 2016). This is mainly caused by the sampling step of discrete latent variables which results in high variance, especially at the early stage of training when both encoder and decoder parameters are far from optimal. Intuitively, the score function \(l(x, a)\) weights the gradient for each latent sample \(a\), and its variance plays a crucial role in updating the parameters in the M-step.

To reduce the variance of the score function and stabilize learning, previous work (Mnih and Gregor, 2014; Miao and Blunsom, 2016; Miao, Yu, and Blunsom, 2016) adopts the baseline method (RL-BL), re-defining the score function as:
\[
l_{RL-BL}(x, a) = l(x, a) - b(x) - b \tag{17}
\]

where \(b(x)\) is a parameterized, input-dependent baseline (e.g., a neural language model in our case) and \(b\) is the bias. The baseline method is able to reduce the variance to some extent, but also introduces extra model parameters that complicate optimization. In the following we propose an alternative generic method for reducing the variance of the gradient estimator in the M-step, as well as another task-specific method which results in further improvement.

**Generic Method**

The intuition behind the generic method is as follows: the algorithm takes \(M\) latent samples for each input \(x\) and a score \(l(x, a^{(m)})\) is computed for each sample \(a^{(m)}\) hence the variance can be reduced by normalization within the group of samples. This motivates the following normalized score function \(l_{RL-SN}(x, a)\):
\[
l_{RL-SN}(x, a) = \frac{l(x, a) - \bar{l}(x, a)}{\max(1, \sqrt{\text{Var}[l(x, a)]})} \tag{18}
\]

**Task-Specific Method**

Besides the generic variance reduction method which applies to discrete neural variational inference in general, we further propose to enhance the quality of the score function \(l_{RL-SN}(x, a)\) for the specific dependency grammar induction task.

Intuitively, the score function in (16) weights the gradient of a given sample \(a\) by a positive or negative value, while \(\gamma(x, a)\) only weights the gradient by a positive value. As a result, the score function plays a much more significant role in determining the optimization direction. Therefore, we propose to correct the polarity of our \(l_{RL-SN}(x, a)\) with the number of rules \(s(x, a) = -\text{SUM}[\phi(x, a)]\) that occur in the induced dependency structure, where \(\text{SUM}\) returns the sum of vector elements. The refined score function is:
\[
l_{RL-PC}(x, a) = \left\{ \begin{array}{ll}
|l_{RL-SN}(x, a)| & \hat{s}(x, a) \geq 0 \\
-l_{RL-SN}(x, a) & \hat{s}(x, a) < 0
\end{array} \right. \tag{19}
\]

where \(\hat{s}(x, a) = \frac{s(x, a) - \bar{s}(x, a)}{\sqrt{\text{Var}[s]}}\).

Since \(\hat{s}(x, a)\) provides a natural corrective, we can obtain a simpler variant of (19) by directly using \(\hat{s}(x, a)\) as the score function:
\[
l_{RL-C}(x, a) = \hat{s}(x, a) \tag{20}
\]

We will experimentally compare the different variance reduction techniques (or score functions) of the reinforcement learning objective.

**Experiments**

**Datasets, Universal Rules, and Setup**

**English Penn Treebank** We use the Wall Street Journal (WSJ) section of the English Penn Treebank (Marcus, Marcinkiewicz, and Santorini, 1993). The dataset is pre-processed to strip off punctuation. We train our model on training sentences (WSJ).

**Datasets, Universal Rules, and Setup**

**Universal Dependency Treebank** We select eight languages from the Universal Dependency Treebank 1.4 (Nivre et al., 2016). We train our model on training sentences of length \(\leq 10\) and report DDA on test sentences of length \(\leq 10\) (WSJ-10), and on all sentences (WSJ).

**Universal Rules** We employ the universal linguistic rules of Naseem et al. (2010) and Noji, Miyao, and Johnson (2016) for WSJ and the Universal Dependency Treebank, respectively (details can be found in the Supplementary Material). For WSJ, we expand the coarse rules defined in Naseem et al. (2010) with the Penn Treebank fine-grained part-of-speech tags. For example, Verb is expanded as \(VB, VBD, VBG, VBN, VBP\) and \(VBZ\).
Problem since no gold annotations exist to "warm up" start.

Pretraining

Unsupervised models in general face a posterior regularization in incorporating such knowledge. Table 2 (to be discussed next) reveals the effectiveness of constrained. A comparison with posterior-regularized results in lexicalized and lexicalized versions) fails to beat the left- and right-branching baseline (Mnih and Gregor, 2014; Miao and Blunsom, 2016) and employing baseline with a conventional inference, using the standard REINFORCE objective (Bertsekas, 1999) to optimize the parameters of posterior regularization.

We use GloVe embeddings (Pennington, Socher, and Manning, 2014) to initialize English word vectors and FastText embeddings (Bojanowski et al., 2016) for the other languages. Across all experiments, we test both unlexicalized and lexicalized versions of our models. The unlexicalized versions use gold POS tags as model inputs, while the lexicalized versions additionally use word tokens (Le and Zuidema, 2015). We use Brown clustering (Brown et al., 1992) to obtain additional features in the lexicalized versions (Buys and Blunsom, 2015).

We report average DDA and best DDA over five runs for our main parsing results.

Exploration of Model Variants

Posterior Regularization To study the effectiveness of posterior regularization in the neural grammar induction model, we first implement a fully unsupervised model without posterior regularization. This model is trained with variational inference, using the standard REINFORCE objective with a baseline (Mnih and Gregor, 2014; Miao and Blunsom, 2016; Miao, Yu, and Blunsom, 2016) and employing no posterior regularization.

Table 1 shows the results for the unsupervised model, together with the random and left- and right-branching baselines. We observe that the unsupervised model (both the unlexicalized and lexicalized versions) fails to beat the left-branching baseline. These results suggest that without any prior linguistic knowledge, the trained model is fairly unconstrained. A comparison with posterior-regularized results in Table 2 (to be discussed next) reveals the effectiveness of posterior regularization in incorporating such knowledge.

Pretraining Unsupervised models in general face a cold-start problem since no gold annotations exist to "warm up" the model parameters quickly. This can be observed in (16): the gradient updates of the model are dependent on the score function \( l \), which in return relies on the model parameters. At the beginning of training we cannot obtain an accurately approximated \( l \) for updating model parameters. To alleviate this problem, one approach is to ignore the score function in the gradient update at the early stage. In this case, both the encoder and decoder are trained with the direct reward from PR (detailed equations can be found in the Supplementary Material). We test the effectiveness of this approach, which we call pretraining.

Table 2 shows the results of a standard posterior-regularized model compared to one only with pretraining. Both models use the unlexicalized setup. We find that the posterior-regularized model benefits a lot from pretraining, which therefore is a useful way to avoid cold start.

Variance Reduction Previously, we described various variance reduction techniques (or score functions) on the WSJ-10 test set. We report the average DDA \( \mu \) and its standard deviation \( \sigma \) over five runs.

The experimental results in Table 3 show that RL-SN outperforms RL-BL on average DDA, which indicates that sample normalization is more effective in reducing the variance of the gradient estimator. We believe the gain comes from the fact that sample normalization does not introduce extra model parameters, whereas RL-BL does. Polarity correction further boosts performance. However, polarity correction uses the number of universal rules present in a induced dependency structure, i.e., it is a task-specific method for variance reduction. Also RL-C (the simplified version of RL-PC) achieves competitive performance.

Universal Rules In our PR scheme, the rule expectations can be uniformly initialized. This approach does not require any annotated training data; the parser is furnished only with a small set of universal linguistic rules. We call this setting

Table 5: Comparison of our models (UNIVERSALRULES and L-WEAKLYSUPERVISED) with previous work on the English Penn Treebank. H1 and H2 are two heuristics used in Rasooli and Faili (2012).

UNIVERSALRULES.

However, we can initialize the rule expectation non-uniformly, which allows us to introduce a degree of supervision into the PR scheme. Here, we explore one way of doing this: we assume a training set that is annotated with dependency rules (the training portion of the WSJ), based on which we estimate expectations for the universal rules. We call this setting WEAKLYSUPERVISED.

The results of an experiment comparing these two settings is shown in Table 4. In both cases we use pretraining and the best performing score function RL-PC. Here we report results using both unlexicalized and lexicalized settings. It can be seen that the best performing UNIVERSALRULES model is the unlexicalized one, while the best WEAKLYSUPERVISED model is lexicalized. Overall, WEAKLYSUPERVISED outperforms UNIVERSALRULES, which demonstrates that our posterior regularized parser is able to effectively use weak supervision in the form of an empirical initialization of the rule expectations.

Parsing Results

English Penn Treebank We compare our unsupervised UNIVERSALRULES model and its WEAKLYSUPERVISED variant with (1) the state-of-the-art unsupervised transition-based parser of Rasooli and Faili (2012), denoted as RF, and (2) two state-of-the-art unsupervised graph-based parsers with universal linguistic rules: Convex-MST (Grave and El-hadad, 2015) and HDP-DEP (Naseem et al., 2010). Both of these are not transition-based, and thus not directly comparable to our approach, but are useful for reference.

The parser of Rasooli and Faili (2012) is unlexicalized and count-based. To reach the best performance, the authors employed “baby steps” (i.e., they start training on short sentences and gradually add longer sentences (Spitkovsky, Al-shawi, and Jurafsky, 2009)), as well as two heuristics called H1 and H2. H1 involves multiplying the probability of the last verb reduction in a sentence by $10^{-0.1}$. H2 involves multiplying each Noun $\rightarrow$ Verb, Adjective $\rightarrow$ Verb, and Adjective $\rightarrow$ Noun rule by 0.1. These heuristics seem fairly ad-hoc; they presumably bias the probability estimates towards more linguistically plausible values.

As the results in Table 5 show, our UNIVERSALRULES model outperforms RF on both WSJ-10 and full WSJ, achieving a new state of the art for transition-based dependency grammar induction. The RF model does not use universal rules, but its linguistic heuristics play a similar role, which makes our comparison fair. Note that our L-WEAKLYSUPERVISED model achieves a further improvement over UNIVERSALRULES, making it comparable with Convex-MST and HDP-DEP, demonstrating the potential of the neural, transition-based dependency grammar induction approach, which should be even clearer on large datasets.

Universal Dependency Treebank Our multilingual experiments use the UD treebank. There we evaluate the two models that perform the best on the WSJ: the unlexicalized UNIVERSALRULES model and lexicalized L-WEAKLYSUPERVISED model. We use the same hyperparameters as in the WSJ experiments. Again, we mainly compare our models with the transition-based model RF (with heuristics H1 and H2), but we also include the graph-based Convex-MST and LC-DMV models for reference.

Table 6 shows the UD treebank results. It can be observed that both UNIVERSALRULES and L-WEAKLYSUPERVISED significantly outperform the RF on both short and long sentences. The improvement of average DDA is roughly 20% on sentences of length $\leq 40$. This shows that although the heuristic approach employed by Rasooli and Faili (2012) is useful for English, it does not generalize well across languages, in contrast to our posterior-regularized neural networks with universal rules.

Parsing Speed To highlight the advantage of our linear time complexity parser, we compare both lexicalized and unlexicalized variants of our parser with a representative DMV-based model (LC-DMV) in terms of parsing speed. The results in Table 7 show that our unlexicalized parser results in a 1.8-fold speed-up for short sentences (length $\leq 15$), and a speed-up of factor 16 for long sentences (full length). And our parser does not lose much parsing speed even in a lexicalized setting.

Related Work

In the family of graph-based models, besides LC-DMV, Convex-MST, and HDP-DEP, a lot of work has focused on improving the DMV, such as adding more types of valence (Headden III, Johnson, and McClosky, 2009), training with artificial negative examples (Smith and Eisner,

Table 7: Parsing speed (tokens per second) on the French UD Treebank with test sentences of various lengths. All experiments were conducted on the same CPU platform.

2005), and learning initial parameters from shorter sentences (Spitkovsky, Alshawi, and Jurafsky, 2009). Among graph-based models, there is also some work conceptually related to our approach. Jiang, Han, and Tu (2017) combine a discriminative and a generative unsupervised parser using dual decomposition. Cai, Jiang, and Tu (2017) use CRF autoencoder for unsupervised parsing. In contrast to these two approaches, we use neural variational inference to combine discriminative and generative models.

For transition-based models, Daumé III (2009) introduces a structure prediction approach and Rasooli and Faili (2012) propose a model with simple features based on this approach. Recently, Shi, Huang, and Lee (2017) and Gomez-Rodriguez, Shi, and Lee (2018) show that practical dynamic programming-like global inference is possible for transition-based systems using a minimal set of bidirectional LSTM features. These models achieve competitive performance for projective or non-projective supervised dependency parsing but have not been applied to unsupervised parsing.

Conclusions

In this work, we propose a feature-rich transition-based parser with sampling-based inference for dependency grammar induction. To enhance performance, we introduce posterior regularization, allowing us to incorporate a small number of universal linguistic rules, which in combination with variance reduction techniques results in a new state of the art for unsupervised transition-based dependency parsing. Meanwhile, our parser retains linear time complexity and reaches significantly faster parsing speed compared to graph-based models. Moreover, we show that it is straightforward to integrate weak supervision into our model in the form of rule expectations.

In future work, we plan to apply our model on much larger corpora, taking advantage of its high parsing speed. Having more training data should result in a further boost in parsing accuracy. On the other hand, inspired by recent work on global inference for supervised transition-based parsing, we also plan to explore the use of more time-consuming global inference in our framework for improved inference.
