Abstract

Plotkin and Pretnar’s handlers for algebraic effects occupy a sweet spot in the design space of abstractions for effectful computation. By separating effect signatures from their implementation, algebraic effects provide a high degree of modularity, allowing programmers to express effectful programs independently of the concrete interpretation of their effects. A handler is an interpretation of the effects of an algebraic computation. The handler abstraction adapts well to multiple settings: pure or impure, strict or lazy, static types or dynamic types.

This is a position paper whose main aim is to popularise the handler abstraction. We give a gentle introduction to its use, a collection of illustrative examples, and a straightforward operational semantics. We describe our Haskell implementation of handlers in detail, outline the ideas behind our OCaml, SML, and Racket implementations, and present experimental results comparing handlers with existing code.

Keywords algebraic effects; effect handlers; effect typing; monads; continuations; Haskell; modularity

1. Introduction

Monads have proven remarkably successful as a tool for abstraction over effectful computations. However, monads as a programming language primitive violate the fundamental encapsulation principle: program to an interface, not to an implementation.

Modular programs are constructed using abstract interfaces as building blocks. This is modular abstraction. To give meaning to an abstract interface, we instantiate it with a concrete implementation. Given a composite interface, each sub-interface can be independently instantiated with different concrete implementations. This is modular instantiation.

The monadic approach to functional programming takes a concrete implementation rather than an abstract interface as primitive. For instance, in Haskell we might define a state monad:

```
newtype State s a = State {runState :: (a, s) -> (a, s)}
instance Monad (State s) where
  return x = State (λs → (x, s))
  m >>= f = State (λs → let (x, s') = runState m s in runState (f x) s')
```

This definition says nothing about the intended use of State s a as the type of computations that read and write state. Worse, it breaks abstraction as consumers of state are exposed to its concrete implementation as a function of type s → (a, s). We can of course define the natural get and put operations on state, but their implementations are fixed.

Jones advocates modular abstraction for monads in Haskell using type classes. For instance, we can define the following interface to abstract state computation:

```
class Monad m ⇒ MonadState s m | m → s where
  get :: m s
  put :: s → m ()
```

The MonadState interface can be smoothly combined with other interfaces, taking advantage of Haskell’s type class mechanism to represent type-level sets of effects.

Monad transformers provide a form of modular instantiation for abstract monadic computations. For instance, state can be handled in the presence of other effects by incorporating a state monad transformer within a monad transformer stack.

A fundamental problem with monad transformer stacks is that once a particular abstract effect is instantiated, the order of effects in the stack becomes concrete, and it becomes necessary to explicitly lift operations through the stack. Taming the monad transformer stack is an active research area.

Instead of the top-down monad transformer approach, we take a bottom-up approach, simply adding the required features as language primitives. We want modular abstraction, so we add abstract effect interfaces, in fact abstract operations, as a language primitive. Abstract operations compose, yielding modular abstraction. We also want modular instantiation, so we add effect handlers as a language primitive for instantiating an abstract operation with a concrete implementation. A handler operates on a specified subset of the abstract operations performed by an abstract computation, leaving the remainder abstract, and yielding modular instantiation.

By directly adding the features we require, we obtain modular abstraction and modular instantiation while avoiding many of the pitfalls of monad transformers.

Our first inspiration is the algebraic theory of computational effects. Introduced by Plotkin and Power, it complements Moggi’s monadic account of effects by incorporating abstract effect interfaces as primitive. Our second inspiration is the elimination construct for algebraic effects, effect handlers. In Plotkin and Power’s setting, one defines algebraic effects with respect to an equational theory. As with other handler implementations, we introduce

\[1\] From the Monad Transformer Library.
in this paper we always take the equational theory to be the free theory, in which there are no equations.

We argue that algebraic effects and effect handlers provide a compelling alternative to monads as a basis for effectful programming across a variety of functional programming languages (pure or impure, strict or lazy, statically typed or dynamically typed). Our position is supported by a range of handler libraries we have implemented for Haskell, OCaml, SML, and Racket, backed up by a core calculus of effect handlers with a straightforward operational semantics. This paper focuses on the Haskell library.

Our key contributions are the following:

- A collection of novel features for practical programming with handlers in the presence of effect typing, illustrated through a series of examples.
- A small-step operational semantics for effect handlers.
- A type and effect system for effect handlers.
- Effect handler libraries for Haskell, OCaml, SML, and Racket.
- A performance comparison between our Haskell library and equivalent non-handler code.

The rest of the paper is structured as follows. Section 2 presents handlers in action through a series of small examples. Section 3 introduces our core calculus of effect handlers, \( \lambda_{\text{eff}} \), its effect type system, and small-step operational semantics. Section 4 presents in detail the Haskell effect handlers library, and sketches the design of our libraries for OCaml, SML, and Racket. Section 5 reports on the baseline performance of handlers in comparison with existing (less abstract) code. Section 6 discusses related work, and Section 7 concludes.

2. Handlers in Action

We present our examples in a monadic style, using an extension to Haskell syntax implemented using the Template Haskell \[40\] and quasiquotes \[28\] features of GHC. Haskell’s features allow for a relatively simple, user-friendly and efficient implementation of effects handlers with effect typing in an existing language. (None of our other libraries support effect typing.)

However, all of the examples could in fact be implemented with the same level of expressivity and flexibility in a direct-style, without any monadic boilerplate. Indeed, handlers can be direct-style with or without effect typing, and provide a natural abstraction for adding more controlled effectful computations to the ML family of languages or even to the Lisp family of languages as witnessed by the libraries we have implemented in OCaml, SML, and Racket. In Section 5, we outline a practical method to prototype an implementation of handlers for a large set of such languages.

A key reason for focusing on our Haskell library in this paper is that it is the only one that supports effect typing. Effect typing is crucial to the termination of our core calculus (Section 3). More importantly, it is crucial for our notion of soundness, as it statically ensures that operations do not accidentally go unhandled. Anecdotally, we have observed that such static guarantees are important in practice: when we added effect typing to an early version of our Haskell library, it revealed a number of bugs in our test examples.

The code for our effect handler libraries, examples, and benchmarks is available in the GitHub repository at:

http://github.com/slindley/effect-handlers/

This repository also includes many other examples. For instance, we have reimplemented Kiselyov and Shan’s HANSEI DSL for probabilistic computation \[22\], Kiselyov’s iterates \[21\], and González’s Pipes library \[14\], all using handlers.

Template Haskell and Quasiquotes Template Haskell \[40\] is a facility for compile-time meta programming in Haskell. It provides a data type for manipulating Haskell code as an abstract syntax tree. It also provides constructs for splicing chunks of Haskell together. Quasiquotes \[28\] extend Template Haskell splicing functionality with user-defined syntax. Each syntax extension (also known as “quasiquoter”) is associated with a name. To define syntax extension, ext, a library writer supplies a parser for ext expressions as a function that takes a string and returns a Haskell abstract syntax tree. To invoke the syntax extension, a programmer writes an expression \( \varepsilon \) in quasiquote brackets \( \text{ext} [\varepsilon] \), a quasiquote. At compile-time, GHC runs the parser on \( \varepsilon \) and splices in the resulting abstract syntax tree in place of the quasiquote brackets.

2.1 State and Handlers

We introduce the primitives for abstract operations and handlers in our Haskell library through the example of global state.

We define abstract operations for state with the following operation quasiquotes

\[
\begin{align*}
\text{operation} & \mid \text{Get } s :: \text{s} \\
\text{operation} & \mid \text{Put } s :: \text{s} \to ()
\end{align*}
\]

which declare a \( \text{Get } s \) operation that takes no parameters and returns values of type \( s \), and a \( \text{Put } s \) operation that takes a single parameter of type \( s \) and returns values of type \( () \). In general an abstract operation declaration has the form

\[
\text{operation} \mid \forall u_1 \ldots u_k.\text{Op } e_1 \ldots e_n :: A_1 \to \ldots \to A_n \to A
\]

where \( \text{Op} \) is the name of the operation, \( u_1, \ldots, u_k \) are universal type variables, \( e_1, \ldots, e_n \) are existential type variables, \( A_1, \ldots, A_n \) are parameter types, and \( A \) is the return type. (We will discuss the role of universal and existential type variables in Section 2.2.)

The declarations above automatically derive wrappers \( \text{get} \) and \( \text{put} \) for actually invoking the operations. Ideally, we would like their types to be

\[
\begin{align*}
\text{get} & :: \text{Comp'} \text{[Get } s \text{]} s \\
\text{put} & :: s \to \text{Comp'} \text{[Put } s \text{]}()
\end{align*}
\]

where \( \text{Comp'} \varepsilon \) is the type of abstract computations that can perform abstract operations in the set \( \varepsilon \) and return a value of type \( a \). But GHC does not have a built-in effect type-system, so we simulate one, encoding sets of operations as type class constraints. Thus, \( \text{get} \) and \( \text{put} \) actually have slightly more complicated types:

\[
\begin{align*}
\text{get} & :: \text{Comp'} \text{[handles \{ Get } s \text{\}}] \Rightarrow \text{Comp } h \text{ s} \\
\text{put} & :: \text{Comp'} \text{[handles \{ Put } s \text{\}}] \Rightarrow s \to \text{Comp } h \text{ ()}
\end{align*}
\]

We can think of the type variable \( h \) as standing for a set of operations, an effect set \( \varepsilon \). Membership of operation \( \text{Op} \in \varepsilon \) is denoted by the quasiquotation \( \text{[handles \{ Op \}}] \) (which is desugared into a corresponding type class constraint). The reason we write \( \text{handles} \) instead of \( \text{contains} \), and \( h \) instead of \( \varepsilon \), is that \( h \) is more than just an effect set; it actually ranges over handlers for \( \varepsilon \). Thus \( \text{Comp } h \) represents computations interpreted by handlers of type \( h \), and the constraint \( \text{[handles \{ Op \}}] \) really means: handler \( h \) handles operation \( \text{Op} \). (We will introduce the syntax for handlers shortly.)

We define the type of abstract state computations as follows:

\[
\text{type SComp } s \ a = \text{vh.\{handles \{ Get } s \text{\}}] \Rightarrow \text{Comp } h \ a
\]

For example:

\[
\text{SComp} s \ a = \text{vh.\{handles \{ Get } s \text{\}}] \Rightarrow \text{Comp } h \ a
\]
Because Haskell is lazy we still require notation for explicitly
sequencing computations. We take advantage of the existing do
notation, and Comp h is implemented as a certain kind of universal
monad (see Section 4).

We can provide many concrete interpretations of stateful com-
putation, which is where handlers come in. First, we interpret state
in the standard monadic way:

```
1 | handler |
2    RunState s a :: s → (a, s)
3    handles { Get s, Put s } where
4    Return x s → (x, s)
5    Get k s → k s s
6    Put s k _ → k () s []
```

We describe the syntax line by line.

Line 1 begins a handler quasiquote.

Line 2 specifies the name, type parameters, and type signature of
the handler. Notice that the type signature s → (a, s) is that of the
state monad. The type signature indicates that this handler takes
one parameter of type s, which is threaded through the handler,
and returns a result of type (a, s).

Line 3 specifies the set of operations handled by the handler.

Line 4 is a return clause. It expresses how to return a final value
from a computation. In general, a return clause takes the form
Return x s → (x, s), where x binds the value returned by
the computation and y binds the return value parameter. Here,
the final value is paired up with the state parameter.

Lines 5 and 6 are operation clauses. They express how to handle
each operation. In general, an operation clause takes the form
Op x1 ... x[n] k y1 ... y[n] → e, where x1, ..., x[n] bind the
operation parameters, k binds the continuation of the computation,
and y1, ..., y[n] bind the handler parameters. Here, the single state
parameter. The continuation k is a curried function which takes
a return value followed by a sequence of handler parameters, and
yields the interpretation of the rest of the computation. For Get,
the return value is the current state, which is threaded through
the rest of the computation. For Put s, the existing state is ignored,
the return value is (), and the state parameter is updated to s.

Analogously to abstract operation declarations, a handler decla-
ration generates a convenient wrapper, whose name is derived from
that of the handler by replacing the first letter with its lower case
counterpart.

```
runState :: SComp s a → (a, s)
```

If we do not need to read the final contents of the state, then we
can give a simpler interpretation to state [45], using the type that
a Haskell programmer might normally associate with a read-only
state monad:

```
| handler |
| EvalState s a :: s → a handles { Get s, Put s } where |
| Return x s → x |
| Get k s → k s s |
| Put s k _ → k () s [] |
```

More interestingly, we can give other interpretations:

```
| handler |
| LogState s a :: s → (a, [s]) handles { Get s, Put s } where |
| Return x s → (x, []) |
| Get k s → k s s |
| Put s k _ → let (x, ss) = k () s in (x, s : ss) [] |
```

This handler logs the history of all writes to the state. For instance,

```
*Main> logState [] comp (4, [2, 4])
```

2.2 State and Open Handlers

The three handlers of Section 2.1 are closed. They each handle
Get and Put, but cannot interpret computations that might perform
other operations. Thus they do not support modular instantiation.

Open handlers extend closed handlers by automatically for-
warding all operations that are not explicitly handled. For instance,
the following defines a handler that forwards all operations other
than Get and Put:

```
| handler |
| forward h. |
| OpenState s a :: s → s handles { Get s, Put s } where |
| Return x s → return x |
| Get k s → return k |
| Put s k _ → return () s [] |
```

The type variable h is an artefact of the Haskell implementation.
It represents an abstract parent handler that will ultimately handle
operations forwarded by OpenState. It is implicitly added as the
first type argument to OpenState (yielding OpenState h s a)
and Comp h is implicitly applied to the return type (yielding
OpenState h a). Any operations other than Get or Put will be
automatically forwarded to h.

To illustrate the compositability of open handlers, we return to
the logging example. In Section 2.1, we demonstrated how to log
Put operations using a special handler. We now factor the logging
in such a way that we can refine any abstract stateful computation
into an equivalent abstract computation that also performs logging,
such that both logging and state can be subsequently interpreted in
arbitrary ways using suitable handlers.

First we define a new operation for logging each Put:

```
| operation |
| LogPut s :: s → () |
```

Now we can define an open handler that inserts a LogPut opera-
tion before every Put operation in the original computation, but
otherwise leaves it unchanged:

```
| handler |
| forward h handles { Put s, LogPut s } |
| PutLogger s a :: a handles { Put s } where |
| Return x s → return x |
| Put s k _ → do { LogPut s; put k () [] } |
```

For instance, the computation putLogger comp is equivalent to:

```
| do { x ← get; LogPut (x + 1); put (x + 1); |
| y ← get; LogPut (y + y); put (y + y); get } |
```

The constraint (h handles { Put s, LogPut s }) asserts that the
parent handler h must also handle the Put s and LogPut s opera-
tions.

To obtain the original behaviour of LogState, we can define the
following open handler:

```
| handler |
| forward h. |
| LogPutReturner s a :: (a, [s]) handles { LogPut s } where |
| Return x s → return (x, []) |
| LogPut s k _ → do (x, ss) ← k (); return (x, s : ss) [] |
```

1Under the hood this aids GHC type inference.
and compose several handlers together:

\[
\text{stateWithLog} :: s \to \text{SComp} s a \to \{a, [s]\}
\]

\[
\text{stateWithLog} s \text{COMP} = (\text{handlePure} \circ \text{logPutReturner} \circ \text{openState} s \circ \text{putLogger}) \circ \text{comp}
\]

where \(\text{HandlePure}\) is a canonical top-level closed handler:

\[
\begin{align*}
\text{[handler]} \\
\text{HandlePure} a :: a \text{ handles } \{\} \text{ where } \text{Return} x \to x \]]
\end{align*}
\]

which interprets a pure computation as a value of type \(a\).

An alternative interpretation of logging is to output logging messages as they arrive:

\[
\begin{align*}
\text{[handler]} \\
\text{forward } h \text{ handles } \{\text{io}\} \text{ where } \text{LogPutPrinter} s a :: a \text{ handles } \{\text{LogPut} s\} \text{ where } \\
\text{Return x} \to \text{return x} \\
\text{LogPut s k} \to \\
\text{do} \text{ io } (\text{putStrLn} (\text{"Put: "} + \text{show s})); k () ]
\end{align*}
\]

Now we can plug everything together:

\[
\begin{align*}
\text{statePrintLog} :: \text{Show} s \Rightarrow s \to \text{SComp} s a \to \text{IO a} \\
\text{statePrintLog s comp} = (\text{handleIO} \circ \text{logPutReturner} \circ \text{openState} s \circ \text{putLogger}) \circ \text{comp}
\end{align*}
\]

where \(\text{HandleIO}\) is another top-level closed handler for performing arbitrary operations in the \(\text{IO}\) monad with the \(\text{IO}\) operation:

\[
\begin{align*}
\text{[operation]} \forall a. \text{IO a} \to a \]]
\end{align*}
\]

\[
\begin{align*}
\text{[handler]} \\
\text{HandleIO a :: IO a handles } \{\text{IO}\} \text{ where } \\
\text{Return x} \to \text{return x} \\
\text{IO m} \to k \Rightarrow \text{do } (x \leftarrow m; k x) ]
\end{align*}
\]

The \text{universal quantifier} in the \(\text{IO}\) operation declaration indicates that it must be handled polymorphically in \(a\). This is in contrast to the declaration of \(\text{Get}\), for instance:

\[
\begin{align*}
\text{[operation]} \forall s. \text{SComp s a} \to a \]]
\end{align*}
\]

where the type parameter \(s\) is \(\text{existential}\), in the sense that for any handler that handles \(\text{Get}\), there must exist a fixed type for \(s\). Correspondingly, in any given abstract computation, \(\text{IO}\) can be used at arbitrary types \(a\) whereas \(\text{Get}\) must be used at a fixed type \(s\).

Comparing the outputs on our sample computation we obtain:

- \texttt{Main> stateWithLog 1 comp}
  
  (4, [2, 4])

- \texttt{Main> statePrintLog 1 comp}
  
  Put: 2
  
  
  Put: 4

The pattern of precomposing one closed top-level handler with a sequence of open handlers is common when using our library. The order in which open handlers are composed may or may not change the semantics. For instance, if we were to swap the order of \(\text{openState} s\) and \(\text{putLogger}\) in \(\text{statePrintLog}\) then all of the \(\text{Put}\) operations would be handled before any \(\text{PutLog}\) operations could be generated, so no logging information would ever be output. On the other hand, if we were to swap the order of \(\text{logPutPrinter}\) and \(\text{openState} s\) then the semantics would be unchanged as their actions are orthogonal.

Open handlers allow us to handle a subset of the effects in an abstract computation, thus supporting modular instantiation.

The next three subsections present more involved examples, demonstrating the interaction of user-defined effects with various Haskell features.

### 2.3 Choice and Failure

Consider abstract operations \(\text{Choose}\) and \(\text{Failure}\):

\[
\begin{align*}
\text{[operation]} \forall a. \text{Choose :: a} \to a \to a \]]
\end{align*}
\]

\[
\begin{align*}
\text{[operation]} \forall a. \text{Failure :: a} \]]
\end{align*}
\]

The idea is that \(\text{Choose}\) should select one of its two arguments of type \(a\), and \(\text{Failure}\) just aborts. Abstract choice computations are interesting because they admit a range of useful interpretations. Archetypal handlers which we consider include those that enumerate all choices \((\text{AllResults} \text{ below})\) and random sampling \((\text{RandomResult} \text{ below})\). The former is notable as it takes full advantage of the ability for an operation clause to invoke the continuation more than once.

The type of abstract computations over \(\text{Choose}\) and \(\text{Failure}\) is:

\[
\begin{align*}
\text{type CF a} = \forall h. (\text{[handler]} h \text{ [Choose]} \] | \text{[handler]} h \text{ [Failure]} \] |) \Rightarrow \text{Comp} h a
\end{align*}
\]

As a simple example, consider the following program:

\[
\begin{align*}
\text{data Toss} = \text{Heads} | \text{Tails deriving Show} \\
\text{drunkToss :: CF Toss} \\
\text{drunkToss} = \text{do} \{\text{caught } \leftarrow \text{choose True False; if caught then \text{choose Heads Tails else \text{failure}}; \}} \\
\text{drunkTosses n} = \text{replicateM n drunkToss}
\end{align*}
\]

The abstract computation \(\text{drunkToss}\) simulates a drunk performing one coin toss. If the drunk catches the coin then the result of tossing the coin \((\text{Heads} \text{ or } \text{Tails})\) is returned. If the coin falls into the gutter then no result is returned. The \(\text{drunkTosses}\) function repeats the process the specified number of times.

We can write a handler that returns all possible results of a \(\text{CF}\) computation as a list, providing a model of non-determinism:

\[
\begin{align*}
\text{[handler]} \\
\text{AllResults a :: [a] handles } \{\text{Choose, Failure}\} \text{ where } \\
\text{Return x} \to x \\
\text{Choose x y k} \to k x \rightleftarrows k y \\
\text{Failure k} \to ]
\end{align*}
\]

This is the first handler we have seen that uses the continuation non-linearly. The \(\text{Choose}\) operation is handled by concatenating the results of invoking the continuation with each alternative. The \(\text{Failure}\) operation is handled by returning the empty list and ignoring the continuation. For example:

```
*Main> allResults (drunkCoins 2) \\
[[Heads, Heads], [Heads, Tails], [Tails, Heads], [Tails, Tails]]
```

Rather than returning all of the results of a \(\text{CF}\) computation, we might wish to sample a single result at random. In order to keep the implementation of randomness abstract, let us declare a new operation for generating random numbers.

\[
\begin{align*}
\text{[operation]} \text{Rand :: Double} \]]
\end{align*}
\]

We first give a handler for \(\text{Choose}\) alone.

\[
\begin{align*}
\text{[handler]} \\
\text{forward } h \text{ handles } \{\text{Rand}\} \\
\text{RandomResult a :: a handles } \{\text{Choose}\} \text{ where } \\
\text{Return x} \to \text{return x} \\
\text{Choose x y k} \to \text{do } (r \leftarrow \text{getStdRandom random; k } \{\text{if } r < 0.5 \text{ then x else y}\} ]
\end{align*}
\]

Unlike in the \(\text{AllResults}\) handler, the \(\text{Choose}\) operation is handled by supplying one of the arguments to the continuation at random. We can implement randomness using the \(\text{IO}\) monad.

\[
\begin{align*}
\text{[handler]} \\
\text{HandleRandom a :: IO a} \\
\text{handles } \{\text{Rand}\} \text{ where } \\
\text{Return x} \to \text{return x} \\
\text{Rand k} \to \text{do } (r \leftarrow \text{getStdRandom random; k } \{\text{if } r \leq 0.5 \text{ then x else y}\} ]
\end{align*}
\]

Let us now define another open handler for handling \(\text{Failure}\), interpreting the result of a possibly failing computation with a \(\text{Maybe}\) type.
As the body of the handler is pure, there is no need to constrain \( h \) with a `handles` clause. We now compose the above three handlers:

\[
\text{sampleMaybe} :: \text{CF} \ a \rightarrow \text{IO} \ (\text{Maybe} \ a)
\]

\[
\text{sampleMaybe} \comp = (\text{handleRandom} \circ \text{maybeResult} \circ \text{randomResult}) \comp
\]

The `sampleMaybe` function first uses `randomResult` to handle Choose using `Rand`, forwarding `Failure`. Then it uses `maybeResult` to handle `Failure`, forwarding `Rand`. Finally, at the top-level, it uses `handleRandom` to handle `Rand` in the `IO` monad. Here are some example runs:

\[
\text{main}> \text{sampleMaybe} \ (\text{drunkTosses} \ 2)
\]

\[
\text{Nothing}
\]

\[
\text{main}> \text{sampleMaybe} \ (\text{drunkTosses} \ 2)
\]

\[
\text{Just} \ [\text{Heads}, \text{Heads}]
\]

We might decide that rather than stopping on failure, we would like to persevere by trying again:

\[
\text{Persevere} a :: \text{Comp} (\text{Persevere} \ h \ a) \ a \rightarrow a
\]

\[
\text{Persevere} \ h \ a \rightarrow a
\]

\[
\text{handles} (\text{Failure}) \where
\]

\[
\text{Return} \ i \rightarrow \text{return} \ (\text{Just} \ x)
\]

\[
\text{Failure} \ k \ c \rightarrow \text{return} \ [\text{Nothing}]
\]

The parameter to the `Persevere` handler is a computation that must be handled recursively by the handler itself. The `Failure` operation is handled by reinvokeing the handler.

We can now persevere until we obtain a sample.

\[
\text{sample} :: \text{CF} \ a \rightarrow \text{IO} \ a
\]

\[
\text{sample} \comp = \text{handleRandom} \ (\text{persevere} \ comp) \comp
\]

\[
\text{where} \ comp = \text{randomResult} \comp
\]

For instance:

\[
\text{main}> \text{sample} \ (\text{drunkTosses} \ 5)
\]

\[
[\text{Heads}, \text{Heads}, \text{Tails}, \text{Heads}, \text{Tails}]
\]

In practice, one might use a more sophisticated sampling approach to improve performance by avoiding failures.\[22\]

### 2.4 Word Count

The `wc` program counts the number of lines, words and characters in an input stream. We first present the abstract operations required to implement this functionality:

\[
\text{operation} \mid \text{ReadChar} :: \text{Maybe Char} \ |
\]

\[
\text{operation} :: \text{Finished} :: \text{Bool} \ |
\]

The `ReadChar` operation reads a character if available. The `Finished` operation checks whether the input is finished. Given these operations, we can implement a function that reads a line:

\[
\text{readLine} :: \text{[handles]} \mid h \ \{ \text{ReadChar} \} \mid] \Rightarrow \text{Comp} \ h \ \text{String}
\]

\[
\text{readLine} = \text{do} \ mc \leftarrow \text{readChar}
\]

\[
\text{case} \ mc \ of
\]

\[
\text{Nothing} \rightarrow \text{return} \ []
\]

\[
\text{Just} \ '\n' \rightarrow \text{return} \ [\ ]
\]

\[
\text{Just} \ c \rightarrow \text{do} \ cs \leftarrow \text{readLine}; \text{return} \ (c : cs)
\]

Of course, this implementation does not specify where the input is to be read from. We define a handler that reads from a string:

\[\text{We cannot }\eta\text{-reduce }\text{sampleMaybe} \text{ as doing so upsets the GHC type checker.}\]
In practice, one might define other handlers in order to support file input.

Here is a version of wc that uses standard input:

```haskell
wcStdin :: String → ()
wcStdin s =
  let (c, w, l) = handlePure (stringReader s wc) in
  putStrLn $ (show l) ++ " " ++ (show w) ++ " " ++ (show c)
```

In practice, one might define other handlers in order to support file input, network input, or different forms of buffering.

### 2.5 Tail

The `tail` function is defined as follows:

```haskell
tailComp ::
  (| handlers | h { ReadChar } |)|,
  (| handlers | h { Finished } |)|,
  (| handlers | h { SaveLine } |)|,
  (| handlers | h { PrintAll } |)|^{*} → EvalState (Comp h)
tailComp =
  do s ← readLine; SaveLine s
     b ← finished; if b then PrintAll else tailComp
```

With these two operations, implementing an abstract tail computation `tailComp` is straightforward.

```haskell
[operation | SaveLine :: String → ()]
[operation | PrintAll :: ()]
```

We now just need to handle the `SaveLine` and `ReadLine` operations. A naive handler might store all saved lines in memory, and print the last `n` as required. In practice, a more efficient implementation might store only the last `n` lines, using a circular array, say.

### 2.6 Pipes and Shallow Handlers

The behaviour of handlers we have described thus far is such that the continuation of an operation is handled with the current handler (though the parameters passed to the continuation may differ from the current parameters).

Another possible behaviour is for the continuation to return an unhandled computation, which must then be handled explicitly. We call such handlers shallow handlers because each handler only handles one step of a computation, in contrast to Plotkin and Pretnar’s deep handlers. Shallow handlers are to deep handlers as case analysis is to a fold on an algebraic data type.

Shallow handlers sometimes lead to slightly longer code. For example, the `EvalState` handler from Section 2.1 becomes:

```haskell
EvalStateShallow s a :: s → a
  handlers { Get s, Put s } where
    Return x s → x
    Get k s → evalStateShallow (k s) s
    Put s k → evalStateShallow (k s) s
```

The need to call the handler recursively in most clauses is characteristic of the style of program one writes with shallow handlers.

In some situations, it is helpful to have access to the unhandled result of the continuation. Consider pipes as exemplified by Gonzalez’s pipes library [13]. A pipe is a data structure used to represent composable producers and consumers of data. A consumer can `await` data and a producer can `yield` data. A pipe is both a consumer and a producer. It is straightforward to provide such an abstraction with the following operations:

```haskell
wcString :: String → IO ()
wccString s =
  let (c, w, l) = handlePure (stringReader s wc) in
  putStrLn $ (show l) ++ " " ++ (show w) ++ " " ++ (show c)
```

These operations have exactly the same signatures as `Get` and `Put`, but their intended interpretation is different. For instance, `yield y` is in no way equivalent to `yield y`.

To define a plumbing operator that combines a compatible consumer and producer we write two handlers: one handles the downstream consumer and keeps a suspended producer to resume when needed, the other handles the upstream producer and keeps a suspended consumer. These two handlers are straightforward to write using shallow handlers:

```haskell
[shallowHandler]
  forward h, Down s a :: Comp (Up h a) a → a
    handles { Await s } where
      Return x s → return x
      Await k prod → return x
    data Prod s r = Prod (() → Cons s r → r)
  data Cons s r = Cons s (Prod s Prod s Prod s)

  which we use to encode the suspended partner of each computation
    [handler]
    forward h, Down s a :: Prod s (Comp h a) a → a
      handles { Await s } where
        Return x s → return x
        Await k (Prod prod) → return x
      data Prod s r = Prod (() → Cons s r → r)
    [handler]
    forward h, Up s a :: Cons s (Comp h a) a → a
      handles { Yield s } where
        Return x s → return x
        Yield s k cons → cons s (Prod k)
```

resulting in a more complex program. We believe both deep and shallow handlers are useful. For clarity of presentation, we focus on deep handlers in the rest of this paper. In Sections 3–4 and Section 4.2 we outline how shallow handlers differ from the main presentation.

### 2.7 Other Perspectives

In this paper we primarily treat handlers as a flexible tool for interpreting abstract effectful computations. Before we proceed with the rest of the paper we highlight some alternative perspectives on what handlers are.

**Generalised exception handlers.** Benton and Kennedy [3] introduced the idea of adding a return continuation to exception handlers. Their return continuation corresponds exactly to the return clause of an effect handler. Effect handler operation clauses generalise exception handler clauses by adding a continuation argument, providing support for arbitrary effects. An operation clause that ignores its continuation argument behaves like a standard exception handler clause.

**Taming delimited continuations.** A handler invocation delimits the start of a computation. Each operation clause captures the continuation of the computation currently being handled, that is, the continuation up to the invocation point of the handler. Effect handlers modularise delimited continuations by capturing particular patterns of use. As Andrej Bauer, the co-creator of the Eff [2] lan-
Figure 1. Types and Effects of $\lambda_{\text{eff}}$

Figure 2. Syntax of $\lambda_{\text{eff}}$ Terms

Values and computational values are given in Figure 1; the terms are given in Figure 2 and the typing rules are given in Figure 3. In all figures, the interesting parts are highlighted in grey. The unhighlighted parts are standard.

Call-by-push-value makes a syntactic distinction between values and computations. Only value terms may be passed to functions, and only computation terms may compute.

Value types (Figure 1) comprise the value unit type (1), value products ($A_1 \times A_2$), the empty type (0), sums ($A_1 + A_2$), and thunks ($U_E C$). The latter is the type of suspended computations.

Computation types comprise value-returning computations ($F_A$), functions ($A \rightarrow C$), the computation unit type ($\top$), and computation product types ($C_1 \times C_2$). Call-by-push-value includes two kinds of products: computation products, which are eliminated by projection, and value products, which are eliminated by binding.

An effect signature is a mapping from operations to pairs of value types, written as a set of type assignments. Each type assignment $\text{op} : A \rightarrow B$, specifies the parameter type $A$ and return type $B$ of operation $\text{op}$.

A handler type $\Gamma \vdash \text{E} \Rightarrow \text{E'}$ $C$ has a input value type $A$, output computation type $C$, input effect signature $E$, and output effect signature $E'$. A handler of this type handles value-returning computations of type $F A$ that can only perform operations in $E$. The body of the handler itself may only perform operations in $E'$, and its computation type is $C$. Type environments are standard.

Value terms (Figure 1) include variables and value introduction forms. We write $\{ M \}$ for the thunk that represents the suspended computation $M$ as a value. All elimination occurs in computation terms, as is standard for call-by-push-value. We write $\text{split}(V, x_1, x_2, M)$ for the elimination form for value products, which binds the components of the product value $V$ to the variables $x_1$ and $x_2$ in the computation $M$. We write $\langle M_1, M_2 \rangle$ for a computation pair and $\text{pr}_1 M$ for the $i$-th projection of $M$. We write $\text{V}$! for the computation that forces the thunk $V$, that is, runs the computation suspended in $V$. A lambda-abstraction $\lambda x. M$ is not a value, so must be suspended to be passed as an argument.

Function application, products, and projections are standard.

In $\lambda_{\text{eff}}$ operation applications are in continuation-passing-style. An operation application $\text{op} V(x) M$ takes a parameter $V$ and a continuation $\lambda x. M$. The intuition is that the operation $\text{op}$ is applied to the parameter $V$, returning a value that is bound to $x$ in the continuation computation $M$. We restrict the continuation to be a lambda abstraction in order to simplify the operational semantics.

While programming with effects, it is more convenient to work with direct-style application. Direct-style application can be defined in terms of continuation-passing-style application: $\tilde{\text{op}} V = \text{op} V(\lambda x. \text{return } x)$, and vice versa: $\text{op} V(\lambda x. M) = \text{let } x \leftarrow \tilde{\text{op}} V \text{ in } M$. Plotkin and Power call the function $\lambda x. \tilde{\text{op}} x$ underlying a direct-style application the generic effect of $\text{op}$ [35].

A handled computation $M$ with $H$ runs the computation $M$ with the handler $H$. A handler $H$ consists of a return clause $\text{return } x \mapsto M$, and a set of operation clauses of the form $\text{op } p \mapsto N$. The return clause $\text{return } x \mapsto M$ specifies how to handle a return value. The returned value is bound to $x$ in $M$. Each operation clause $\text{op } p \mapsto N$ specifies how to handle applications of the distinct operation name $\text{op}$. The parameter is bound to $p$ and the continuation is bound to $N$. The body of the continuation continues to be handled by the same handler.

The typing rules are given in Figure 3. The computation typing judgement $\Gamma \vdash \text{E} \Rightarrow \text{E'} C : \text{C}$ states that in type environment $\Gamma$ the computation $M$ has type $C$ and effect signature $E$. Only operations in the current effect signature can be applied. Handling a computation changes the current effect signature to the output effect signature of the handler. The effect signature and type of the handled computation must match up exactly with the input type and effect signature of the handler.

In the handler typing judgement $\Gamma \vdash H : \text{R}$, all clauses must have the same output type and effect signature. The input type is determined by the return clause. The effect annotation on the thunked continuation parameter $k$ in an operation clause $\text{op } p \mapsto N$ is annotated with the output effect rather than the input effect. The reason for this is that when handling an operation, the handler is automatically wrapped around the continuation.

Syntactic Sugar For convenience, we define syntactic sugar for projecting out the return clause and operation clauses of a handler. For any handler $\{ \text{return } x \mapsto M \} \cup \{ \text{op } p \mapsto N_i \}$, we write $H^{\text{return}} \equiv \lambda x. M$ and $H^{\text{op}} \equiv \lambda p_i k_i N_i$. 

### Syntax and Static Semantics

The types and effects of $\lambda_{\text{eff}}$ are given in Figure 1; the terms are given in Figure 2 and the typing rules are given in Figure 3. In all figures, the interesting parts are highlighted in grey. The unhighlighted parts are standard.

Call-by-push-value makes a syntactic distinction between values and computations. Only value terms may be passed to functions, and only computation terms may compute.

Value types (Figure 1) comprise the value unit type (1), value products ($A_1 \times A_2$), the empty type (0), sums ($A_1 + A_2$), and thunks ($U_E C$). The latter is the type of suspended computations.

Computation types comprise value-returning computations ($F_A$), functions ($A \rightarrow C$), the computation unit type ($\top$), and computation product types ($C_1 \times C_2$). Call-by-push-value includes two kinds of products: computation products, which are eliminated by projection, and value products, which are eliminated by binding.

An effect signature is a mapping from operations to pairs of value types, written as a set of type assignments. Each type assign-
3.2 Operational Semantics

The reduction relation ($\rightarrow$) for $\lambda_{ef}$ is defined in Figure 3. We use reduction frames as an auxiliary notion to simplify our presentation. The $\beta$-rules are standard; each $\beta$-redex arises as an introduction followed by an elimination. The first three $\beta$-rules eliminate value terms; the last three eliminate computation terms.

The hoist.op-rule hoists operation applications through hoisting frames. Its purpose is to forward operation applications up to the nearest enclosing handler, so that they can be handled by the handle.op-rule.

The handle.F-rule returns a value from a handled computation. It substitutes the returned value into the return clause of a handler in exactly the same way that $\beta.F$-reduction substitutes a returned value into the body of a let binding.

The handle.op-rule is the most involved of the reduction rules. A handled operation application $\text{handle} \ op \ V(\lambda x.M)$ with $H$ reduces to the body of the operation clause $H^{op} = \lambda p. k.N$ with the parameter $V$ substituted for $p$ and the continuation $\lambda x.M$ substituted for $k$. Any further operation applications should be handled by the same handler $H$. Thus, we wrap $H$ around $M$.

The frame-rule allows reduction to take place within any stack of computation frames, that is, inside any evaluation context. The semantics is deterministic, as any term has at most one redex. Furthermore, reduction on well-typed terms always terminates.

Theorem 1 (Termination). If $\Gamma \vdash E \ M : C$ then reduction on $M$ terminates.

Proof sketch: The proof is by a relatively straightforward adaptation of Lindley’s proof of strong normalisation for sums [26]. The interesting rule is handle.op, which reinvokes the handler, possibly many times, but always on a subterm of the original computation. As with Ariola et al.’s normalisation result for delimited continuations [11], termination depends crucially on the effect type system.

Theorem 2 (Type soundness). If $\Gamma \vdash (\cdot) \ M : FA$ then $M$ reduces to a returned value $\text{return} \ V$ of type $A$.

Proof sketch: Define a canonical term to be any computation term of the form: return $V, \lambda x.N$, $\langle \cdot \rangle$, $(V, W)$, or op $V(\lambda x.M)$. Induction on typing derivations shows progress: if $\Gamma \vdash E \ M : C$ then, either there exists $M'$ such that $M \rightarrow M'$, or $M$ is canonical. By appeal to a substitution lemma, induction on typing
derivations shows preservation: if $\Gamma \vdash_E M : C$ and $M \rightarrow M'$
then $\Gamma \vdash_E M' : C$.

3.3 Open Handlers

Our presentation of $\lambda_{\text{eff}}$ gives an operational account of closed handlers. We can adapt $\lambda_{\text{eff}}$ to support open handlers by making two small changes. The typing rule for handlers becomes:

$$\begin{align*}
E &= E' \oplus \{\text{op}_i : A_i \rightarrow B_i\}_i \\
H &= \{\text{return } x \mapsto M\} \uplus \{\text{op}, p k \mapsto N_i\}_i, \\
[\Gamma, p : A_i : k : U_{E'}(B_i \rightarrow C) \uplus E', N_i : C], \\
\Gamma, x : A \vdash E' : M : C \\
\Gamma \vdash H : A \stackrel{E'}{\Rightarrow} C
\end{align*}$$

The only change to the original rule is that the input effects are now $E' \oplus E$ instead of just $E$, where $E' \oplus E$ is the extension of $E'$ by $E$ (where any clashes are resolved in favour of $E$).

The handle $\text{op}$-rule is refined by extending the meaning of $H^{\text{op}}$, such that it is defined as before for operations that are explicitly handled by $H$, but is also defined as $\lambda p k. \text{op} p(\lambda x. k x)$ for any other operation $\text{op}$. This means that any operation that is not explicitly handled is forwarded.

In our simply-typed formalism, it is straightforward to translate any program that uses open handlers into an equivalent program that uses closed handlers. As any open handler handles a bounded number of operations, we can simply write down all of the implicit forwarding clauses explicitly. In practice, it seems desirable to offer both open and closed handlers, as in our Haskell library.

To take full advantage of open handlers in a typed language, one inevitably wants to add some kind of effect polymorphism. Indeed, our Haskell implementation provides effect polymorphism, encoded using type classes. We believe that effect polymorphism can be supported more smoothly using row polymorphism.

We briefly outline one path to supporting row polymorphism. The open handler rule from above can be rewritten as follows:

$$\begin{align*}
E' &= \{\text{op}_i : A_i \rightarrow B_i\}_i \\
E' &= E' \oplus E_f \\
H &= \{\text{return } x \mapsto M\} \uplus \{\text{op}, p k \mapsto N_i\}_i, \\
[\Gamma, p : A_i : k : U_{E'}(B_i \rightarrow C) \uplus E', N_i : C], \\
\Gamma, x : A \vdash E' : M : C \\
\Gamma \vdash H : A \stackrel{E'}{\Rightarrow} C
\end{align*}$$

The key difference is that this version of the rule uses disjoint union $\uplus$ in place of extension $\sqcup$, explicitly naming the collection of forwarded effects. One can now instantiate the meta variable $E_f$ with a row variable. We would likely also wish to support polymorphism over $E'$. This is not difficult to achieve using a Remy-style account of row typing if we insist that $E'$ only include operations in $\{\text{op}_i\}_i$. We leave a full investigation of effect polymorphism for handlers to future work.

3.4 Shallow Handlers

Our presentation of $\lambda_{\text{eff}}$ gives an operational account of deep handlers. In order to model shallow handlers we can make two small changes. The typing rule for handlers becomes:

$$\begin{align*}
E &= \{\text{op}_i : A_i \rightarrow B_i\}_i, \\
E' &= E' \oplus E_f, \\
H &= \{\text{return } x \mapsto M\} \uplus \{\text{op}, p k \mapsto N_i\}_i, \\
[\Gamma, p : A_i : k : U_{E'}(B_i \rightarrow FA) \uplus E', N_i : C], \\
\Gamma, x : A \vdash E' \uplus E' : M : C \\
\Gamma \vdash H : A \stackrel{E'}{\Rightarrow} C
\end{align*}$$

The only changes with respect to the original rule are to the types of the continuations, which now yield $\lambda x. \text{op} x$ computations under the input effect signature $E$, rather than $\lambda x. \text{op} x$ computations under the output effect signature $E'$. The handle $\text{op}$-rule is replaced by the shallow-handle $\text{op}$-rule:

$$\begin{align*}
\text{(shallow-handle) } \text{op} & V = \lambda p k. N \\
H^{\text{op}} &= \lambda p k. N & x \notin FV(H) \\
\text{handle } H \vdash \Gamma \vdash H \in \text{Fun}(\Gamma)
\end{align*}$$

which does not wrap the handler around the continuation. Of course, without recursion shallow handlers are rather weak.

4. Implementation

Any signature of operations can be viewed as a free algebra and represented as a functor. Every such functor gives rise to a free monad (Swierstra [43] gives a clear account of free monads for functional programmers). This yields a systematic way of building a monad to represent computations over a signature of operations.

We use our standard state example to illustrate. Concretely we can define the free monad over state as follows:

$$\begin{align*}
data\ FreeState\ s\ a\ =\ &\ Ret\ a \\
|\ Get\ ()\ (s \mapsto FreeState\ s\ a) \\
|\ Put\ s\ ()\ \mapsto FreeState\ s\ a
\end{align*}$$

instance\ Monad\ (FreeState\ s)\ where

\begin{align*}
\text{return} & = Ret \\
Ret\ v & \gg f = f\ v \\
Get\ ()\ k\ \gg f & = Get\ (\lambda x. k x\ \gg f) \\
Put\ s\ ()\ \gg f & = Put\ s\ (\lambda x. k x\ \gg f)
\end{align*}$$

The type FreeState $s$ a is a particular instance of a free monad. It can be viewed as a computation tree. The leaves are labelled with $\text{Ret} v$ and the nodes are labelled with $\text{Get} ()$ and $\text{Put} s$. There is one edge for each possible return value supplied to the continuation of $\text{Get}$ and $\text{Put}$ — a possibly infinite number for $\text{Get}$ depending on the type of the state, and just one for $\text{Put}$. The bind operation performs a kind of substitution. To compute $c\ \gg f$, the tree $f\ v$ is grafted onto each leaf $\text{Ret} v \in c$.

The generic free monad construction can be defined as follows:

$$\begin{align*}
data\ Free\ f\ a\ =\ &\ Ret\ a \mapsto Do\ (f\ (Free\ f\ a)) \\
instance\ Monad\ (Free\ f)\ where

\begin{align*}
\text{return} & = Ret \\
Ret\ v & \gg f = f\ v \\
Get\ ()\ k\ \gg f & = Get\ ()\ (\lambda x. k x\ \gg f) \\
Put\ s\ ()\ \gg f & = Put\ s\ (\lambda x. k x\ \gg f)
\end{align*}$$

and we can instantiate it with state as follows:

$$\begin{align*}
data\ StateFunctor\ s\ a\ =\ &\ GetF\ ()\ \mapsto (s \mapsto a) \\
|\ PutF\ s\ ()\ \mapsto a
\end{align*}$$

deriving\ Functor

where FreeState $s$ is isomorphic to Free (StateFunctor $s$). A handler for state is now simply a unary function whose argument has type Free (StateFunctor $s$). For instance:

$$\begin{align*}
\text{stateH} \vdash Free\ (\text{StateFunctor}\ s)\ a \mapsto (s \mapsto a) \\
\text{stateH}\ (\text{Ret}\ x) & = \lambda s. x \\
\text{stateH}\ (\text{Do}\ (\text{Get}\ ()\ k)) & = \lambda s. \text{stateH}\ (k\ s) \\
\text{stateH}\ (\text{Do}\ (\text{Put}\ s\ k)) & = \lambda c. \text{stateH}\ (k\ s) \\
\end{align*}$$

interprets a stateful computation as a function of type $s \mapsto a$.

A limitation of the above free monad construction is that it is closed in that it can only handle operations in the signature. A key feature of our library is support for open handlers that handle a fixed set of operations in a specified way, and forward any other operations to be handled by an outer handler. To encode openness in GHC we take advantage of type classes and type families.

The code for open free monads is given in Figure 5. We split the type of each operation into two parts: a type declaration that defines the parameters to the operation, and a type family instance that defines the return type of the operation. For instance:

$$\begin{align*}
\text{operation} |\ Put\ s : s \mapsto a
\end{align*}$$

generates:
data Put (e :: *) (u :: *) where
  Put :: s → Put s ()

type instance Return (Put s ()) = ()

The first type argument e encodes the existential type arguments of an operation, while the second type argument u encodes the universal type arguments of an operation. In the case of Put there is a single existential type argument s and no universal arguments. Using GADTs we can encode multiple arguments as tuples. Handler types are generated similarly.

Lines 1–2 of Figure 5 declare type families for operation return types and handler result types. Lines 3–6 define a ternary type class \(\text{Handles} \) for some \(e\). Each instance of this class defines the clause of handler \(h\) that handles operation \(op\) with existential type arguments bound to \(e\). Of course, we do not supply the universal arguments, as the clause should be polymorphic in them. The functional dependency \(h \ op \to a\) asserts that type \(a\) must be uniquely determined by types \(h\) and \(op\). This is crucial for correctly implementing open handlers as we discuss further in Section 4.2. The \text{handles} quasiquoter generates type class constraints on the \text{Handles} type class.

Lines 7–14 define the monad \(\text{Comp} \) for a handler \(h\), which is simply a free monad over the constructor for a handler type — just as automatically generated continuations can be optimised by composing with the \text{Comp} monad directly, meaning that the \text{do} functional form is now cleaned up.

We are making essential use of the type class mechanism. It is instructive to read the type of \text{handle} as taking a return clause, a list of operation clauses, one for each \(op\) such that \((h \ '\text{Handles}' \) \(op\)) \(e\) for some \(e\), and returning a result. Thus the second argument of type \(h\), as well as providing parameters to the handler, also, albeit indirectly, encodes the list of operation clauses.

The \text{handler} quasiquoter automatically generates a convenient wrapper meaning that programmers need never directly manipulate the constructor for a handler type — just as automatically generated operation wrappers mean that they need never directly manipulate the constructor for an operation type.

Limitations Our Haskell implementation of handlers has several limitations. First, because handlers are encoded as type classes and type classes are not first-class, neither are handlers. Second, because we abstract over handlers in order to simulate effect typing the types of the operation wrappers are more complex than necessary. Third, because we explicitly mention a parent handler in the type of open handlers, the order in which open handlers are composed can leak into types (this is not as bad as with monad transformers, as lifting is never required, but it is still undesirable).

All of these limitations arise from attempting to encode handlers in Haskell. None is inherent to handlers. We believe that a row-based effect type system along the lines of Leroy and Pessaux [23], Blume et al [5], or Lindley and Cheney [27] would provide a cleaner design.

The Codensity Monad It is well known that free monad computations can be optimised by composing with the \text{Codensity} monad, which is essentially the continuation monad over a polymorphic return type [45].

The Continuation Monad We can in fact do even better by using the continuation monad directly, meaning that the \text{Ret} and \text{Do} constructors disappear completely. The continuation monad code is given in Figure 6. The difference from the free monad code begins on Line 7. The type constructor \(\text{Comp} \) is exactly that of the continuation monad with return type \(h \to \text{Result} \ h\). We choose not to factor through the continuation monad defined in the standard library as doing so hurts performance. The \text{handle} function is now exactly the deconstructor for \(\text{Comp}\), while the \text{do} function is just \(\text{Comp} \circ \text{clause}\). We explicitly \(\eta\)-expand \text{do} because GHC is unable to optimise the point-free version.

4.1 Open Handlers and Forwarding

The key trick for implementing forwarding is to parameterise a handler \(H\) by its parent handler \(h\). Without this parameter we would
have no way of describing the operations that are handled by both $H$ and $h$. Now we can define the following type class instance:

```haskell
instance (h `Handles` op) e ⇒ (H h `Handles` op) e where
  clause op k h = doOp op ≻= (λx → k x h)
```

The **handler** quasi-quoter generates this boilerplate automatically for open handlers.

The functional dependency $(H \ h) \ op → e$ is crucial here. Without it GHC would be unable to resolve the `clause` function. For instance, consider the `OpenState` handler. This must select from the following instances for `Get`:

```haskell
instance (OpenState h s a `Handles` Get) s where
  clause Get k (OpenState s) = k s (OpenState s)

instance (h `Handles` Get) t ⇒ (OpenState h s a `Handles` op) t where
  clause op k h = doOp op ≻= (λx → k x h)
```

Without the functional dependency the latter is chosen. This is because GHC tries to ensure that the same version of `clause` is used for `Get t` for any $t$, and the former is only valid if $s$ is equal to $t$. The functional dependency asserts that $t$ must be equal to $s$.

Because the type variable $t$ does not appear in either of the types `OpenState h s a op or`, and there is a functional dependency which states that `OpenState h s a op uniquely determine e`, GHC’s default type inference gives up. Enabling the `UndecidableInstances` language option fixes this. We believe that our basic use of `UndecidableInstances` is well-founded (and decidable!), because of the type class constraint $(h `Handles` op) t$ which implies that $h$ and $op$ already uniquely determine $t$.

### 4.2 Shallow Handlers

It is relatively straightforward to adapt our free monad implementation to implement shallow handlers. The key change is to the type of the continuation argument of the `clause` function which must return a computation. It seems less clear how to adapt the continuation monad implementation.

### 4.3 Delimited Continuations

We now sketch an implementation of (open) effect handlers in terms of delimited continuations [8, 9]. These ideas underlie our OCaml, SML, and Racket implementations.

A variety of different delimited continuation operators are covered in the literature. Shan has recently shown that the four basic choices are straightforwardly inter-definable [8, 9]. We choose to describe our implementation in terms of a minor variant of Danvy and Filinski’s `shift` and `reset` operators [8] called `shift0` and `reset0`. The behaviour of `shift0` and `reset0` can be concisely summarised through the following reduction rule:

\[
\text{reset0} \left( E[\text{shift0} \ (\lambda k. M)] \right) \rightarrow M[(\lambda x. \text{reset0} \ (E[x])/k]/k]
\]

where $E$ ranges over call-by-value evaluation contexts.

The `reset0` operator delimits the start of a continuation, and the `shift0` operator captures the continuation up to the nearest enclosing `reset0`. Crucially, the captured continuation is wrapped in a further `reset0`. It is instructive to compare the above rule with the `handle-op-rule`, where `handle` − with $H$ plays a similar role to `reset0`.

The implementations rely on the following key ingredients:

- A global (or thread-local) variable keeps a stack of handlers in the current dynamic scope.
- Each handler includes a map from the handled operations to the corresponding operation clause.

To handle an effectful computation `handle M` with $H$:

- The handler $H$ is added to the top of the stack.
- We invoke `reset0 \ (H*return M)`.

To apply an operation (in direct style) `op p`:

1. We invoke `shift0` to capture the continuation $k$ up to (but excluding) the next operation handler.
2. The top-most handler $H$ is popped from the stack.
3. We let $k' = \lambda x. \text{push H; reset0} \ (k x)$, where `push H` pushes $H$ back onto the stack.
4. The clause corresponding to the operation, that is $H^{op}$, is applied to the parameter $p$ and the continuation $k'$.
5. If there is no clause corresponding to this operation, it will be forwarded by the handler. If no other handlers enclose the operation, an exception is raised.

To support shallow handlers, one replaces `shift0` and `reset0` with `control0` and `prompt0`, which behave like `shift0` and `reset0`, except no `prompt0` is wrapped around the continuation:

\[
\text{prompt0} \ (E[\text{control0} \ (\lambda k. M)]) \rightarrow M[(\lambda x. E[x])/k]
\]

### 4.4 Dynamic and Static Operations

Our Haskell implementation uses one static type per operation. A program execution cannot dynamically create a new operation. Because they do not provide effect typing, our other implementations do support dynamic operations, which can be created, closed upon and garbage collected. This makes some programs easier to write. For example, references can be represented as pairs of dynamically generated `Put` and `Get` operations. With only static operations, one has to parameterise `Put` and `Get` by some representation of a reference, and explicitly manage all of the state in a single handler.

Static effect typing for dynamic operations presents challenges:

- Writing an effect type system for dynamic operations involves some form of dependent types, as operations are now first-class objects of the language.
- Dynamic operations are difficult to implement as efficiently as static operations. In particular, it is not clear how to use the type system to pass only the relevant effects to each scope.

### 5. Performance Evaluation

To evaluate the performance of our Haskell library, we implemented a number of micro-benchmarks, comparing handler code against monadic code that makes use of existing libraries. The code for the micro-benchmarks can be found in the GitHub repository at:

[http://github.com/slindley/effect-handlers/Benchmarks](http://github.com/slindley/effect-handlers/Benchmarks)

Detailed performance results can be found in Appendix A.

Our primary goal was to check that the handler abstraction does not cripple performance. We rely on GHC to optimise away many of the abstractions we introduce. In the future we envisage building handlers into the core of a programming language. We might reasonably hope to do significantly better than in the library-based approach by tailoring optimisations to be aware of handlers.

The results confirm that the Haskell library performs adequately. The performance of the continuation monad implementation of handlers is typically no worse than around two thirds of baseline code. In some cases the continuation monad implementation actually outperforms existing implementations. The continuation monad implementation always outperforms the free monad implementation (sometimes by more than an order of magnitude), which always outperforms the free monad implementation. Usually standard handlers outperform shallow handlers,
pipes being an exception, where for large numbers of nested sub-pipes shallow handlers outperform even the continuation monad implementation of standard handlers.

6. Related Work

Algebraic Effects and Effect Handlers Effect operations were pioneered by Plotkin and Power [5], leading to an algebraic account of computational effects [34] and their combination [15]. Effect handlers were added to the theory in order to support exception handling [36]. Recent work incorporates additional computational effects within the algebraic framework, for example, local state [41], and applies the algebraic theory of effects to new problem domains, such as effect-dependent program transformations [19], and logical-relations arguments [24].

While mostly denotational in nature, operational accounts of algebraic effects (without handlers) do exist. Plotkin and Power [53] gave operational semantics to algebraic effects in a call-by-value setting, and Johann et al. [32] gave operational semantics to algebraic effects in a call-by-name setting.

Effect Handler Implementations Bauer and Pretnar’s effectful strict statically-typed language Eff [2] has built-in support for algebraic effects and effect handlers. Like our ML implementations, it lacks an effect type system. Eff implements dynamic generation algebraic effects and effect handlers. Like our ML implementations, Eff pioneered by Eff. The core idea is to layer continuation monads in the style of Filinski [10], using Haskell type classes to automatically infer lifting between layers. McBride’s language Frank [29] is similar to Eff, but with an effect system along the lines of ours. It supports only shallow handlers and employs a novel form of effect polymorphism which elides effect variables entirely. Brady [4] has implemented an effect handlers library for the dependently-typed language Idris. It takes advantage of dependent types for resource tracking. The current design has some limitations compared with the other handler implementations. In particular, the composition of other effects with non-determinism is not well-behaved.

Monadic Reflection and Layered Monads Filinski’s work on monadic reflection and layered monads is closely related to effect handlers [11]. Monadic reflection supports a similar style of composing effects. The key difference is that monadic reflection interprets monadic computations in terms of other monadic computations, rather than abstracting over and interpreting operations. Filinski’s system is nominal (an effect is the name of a monad), whereas ours is structural (an effect is a collections of operations).

Monad Transformers and Inferred Lifting Jaskelioff and Moggi [17] develop the theory of monad transformers and lifting of effect operations. Jaskelioff’s Monatron [16] is a monad transformer library based on this development. Schrijvers and Oliveira [38] infer lifting in Haskell using a zipper structure at the level of type classes to traverse the monad transformer stack. Swamy et al. [42] add support for monads in ML, inferring not only where and how to lift operations, but also where to insert return and bind statements. In both approaches, once the required monad transformers have been defined, the desired lifting is inferred automatically.

7. Conclusion

Algebraic effects and handlers provide a promising approach for supporting effectful computations in functional languages. By offering a new form of modularity, they create possibilities for library design and reusability that are just beginning to emerge. This paper shows that implementing these constructs is within the reach of current compiler technology.

Acknowledgments

The λeff calculus stemmed from discussions of the first author with Andrej Bauer and Matija Pretnar in Ljubljana and Swansea.

The authors would like to thank Stevan Andjelkovic, Danel Ahman, Bob Atkey, Andrej Bauer, Brian Campbell, James Cheney, Derek Dreyer, Andrej Filinski, Ben Kavanagh, Neel Krishnaswami, Conor McBride, James McKinna, Gordon Plotkin, Matija Pretnar, Alex Simpson, Sam Staton, Phil Wadler, and the POPL 2013, PLDI 2013, and ICFP 2013 referees, for useful conversations, comments and suggestions. We are grateful to Gabriel Gonzalez for pointing out a flaw in the pipes benchmarks in an earlier draft of this paper. The type system originated from a visit by the first author to Andrej Bauer and Matija Pretnar in Ljubljana, supported by the Laboratory for Foundations of Computer Science. This work was supported by a Google Research Award, EPSRC grants EPSJ014591/1 and EP/H005633/1, a SICSA studentship, an Edinburgh University Informatics School studentship, and an Isaac Newton Trust starter grant.

A. Performance Results

All performance testing was conducted with the -O2 compiler flag enabled using a PC with a quad-core Intel i7-3770K CPU running at 3.50GHz CPU and 32GB of RAM, running GHC 7.6.1 on Ubuntu Linux 12.10. We used O’Sullivan’s criterion library [21] to sample each micro-benchmark ten times.

The code for the micro-benchmarks can be found in the GitHub repository at:

http://github.com/slindley/effect-handlers/Benchmarks

A.1 State

As a basic sanity check we tested the following function on state:

\[
\text{count :: SComp Int Int} \\
\text{count = do i \leftarrow get;} \\
\text{if i \equiv 0 then return i} \\
\text{else do put (i - 1); count}
\]

We used \(10^8\) as the initial value for the state. We tested implementations using: the state monad, three different versions of standard deep handlers, and one implementation of shallow handlers. As a control, we also tested a pure version of \(\text{count}\). In each case we used open handlers for interpreting state.

<td>2550</td>
<td>0.02</td>
</tr>
<tr>
<td>shallow handlers</td>
<td>5530</td>
<td>0.01</td>
</tr>
</tbody>
</table>

Table 1. State

The results are shown in Table 1. GHC is optimised for monadic programming, so there is no cost to using a state monad over a pure program. The continuation monad implementation runs at two thirds of the speed of the baseline. The free monad implementation is a hundred times slower than the baseline. Using a codensity monad gives a two times speed-up to the free monad implementation. Shallow handlers are implemented using a free monad and are slowest of all.

A.2 Flat Pipes

We tested our pipes implementation using a flat pipeline previously used by the author of the pipes library for comparing performance between the pipes library and other libraries [13]. The pipeline consists of a producer that yields in turn the integers in the sequence \([1 \ldots n]\), for some \(n\), connected to a consumer that ignores all inputs and loops forever. The pipes library optionally takes advantage of GHC rewrite rules to define special code optimisations for pipes code. We tested against pipes with and without the rewrite rules enabled. The results are shown in Table 2 for \(n = 10^8\). The continuation monad implementation is nearly twice as fast as the pipes library without rewrite rules enabled. Enabling the rewrite rules makes a significant difference. In this case the pipes library is faster than the continuation monad implementation. The free monad and codensity implementations are slower than the pipes library, but the differential is much smaller than in the case of the count micro-benchmark. Interestingly, shallow handlers outperform the free monad implementation of standard handlers.

Table 2. Flat Pipes

A.3 Nested Pipes

To test the scalability of handlers we implemented a deeply-nested pipes computation constructed from \(2^n\) sub-pipes, for a range of
values of \( n \). The results are shown in Table 3. They are intriguing as the relative performance varies according to the number of sub-pipes. The relative performance is shown graphically in Figure 7. The \( \texttt{pipes} \) library always out-performs all of our libraries, even with GHC rewrite rules disabled. The continuation monad implementation is relatively constant at around two thirds the speed of the \( \texttt{pipes} \) library. What is particularly notable is that as the level of nesting increases, the performance of shallow handlers eventually overtakes that of the continuation monad implementation.

One possible reason for the \( \texttt{pipes} \) library outperforming our continuation monad implementation on nested pipes is that it is in fact based on a free monad, and the implementation takes advantage of the reified representation of computations to optimise the case where an input is forwarded through several pipes.

We are not sure why shallow pipes perform so well on deeply-nested pipes, but suspect it may be due to the simpler definition of pipes for shallow handlers, as compared with that for standard handlers, opening up optimisation opportunities along the lines of those explicitly encoded in the \( \texttt{pipes} \) library.

We conjecture that the anomalous dip at \( 2^{11} \) sub-pipes for the bottom three lines in Figure 7 is due to cache effects.

### A.4 The \( n \)-Queens Problem

To test the performance of handlers that invoke the continuation zero or many times, we implemented the classic \( n \)-queens problem in terms of an \( n \)-ary \texttt{Choose} operation:

\[
\texttt{operation} \mid \forall a. \texttt{Choose} :: [a] \to [a]
\]

We wrote a handler that returns the first correct solution for the \( n \)-queens problem, and tested against a hand-coded \( n \)-queens solver. We tested both algorithms with \( n = 20 \).

<table>
<thead>
<tr>
<th>Implementation</th>
<th>Time (ms)</th>
<th>Relative Speed</th>
</tr>
</thead>
<tbody>
<tr>
<td>hand-coded</td>
<td>160</td>
<td>1.00</td>
</tr>
<tr>
<td>handlers</td>
<td>237</td>
<td>0.67</td>
</tr>
</tbody>
</table>

Table 3. \( n \)-Queens

The results are shown in Table 3. The handler version is about two thirds the speed of the hand-coded version.

### A.5 Aspect-Oriented Programming

Effect handlers can be used to implement a form of aspect-oriented programming. We tested an expression evaluator taken from Oliveira et al.’s work on monadic mixins [7]. The expression evaluator is extended to output logging information whenever entering or exiting a recursive call, and to output the environment whenever entering a recursive call. We compared a hand-coded evaluator with Oliveira et al.’s mixin-based evaluator and an evaluator implemented using our continuation monad implementation of standard handlers. We tested each evaluator on the same randomly generated expression containing \( 2^{12} \) leaf nodes.

<table>
<thead>
<tr>
<th>Implementation</th>
<th>Time (ms)</th>
</tr>
</thead>
<tbody>
<tr>
<td>hand-coded</td>
<td>6516</td>
</tr>
<tr>
<td>mixins</td>
<td>6465</td>
</tr>
<tr>
<td>handlers (continuations)</td>
<td>6526</td>
</tr>
</tbody>
</table>

Table 4. Aspect-Oriented Programming

The results are shown in Table 4. The performance is almost identical for each of the three implementations, indicating no abstraction overhead.
