

# A Bayesian Model of Multi-modal Visuomotor Adaptation

Adrian Haith, Sethu Vijayakumar — School of Informatics, The University of Edinburgh, UK

## Summary

- We propose a model of multi-modal adaptation of reaching movements based on optimal Bayesian inference of the causes of errors
- Our model accounts for the patterns of trial-to-trial adaptation as well as perceptual aftereffects in vision and proprioception when visual feedback is shifted or rotated.

## Motivation

### Perceptual aftereffects of adaptation to shifted visual feedback

Many studies have reported that adaptation to shifted visual feedback induces shifts in both visual and proprioceptive perception [7, 2, 5].

Visual perceptual shift

- Subjects asked to locate a visual or proprioceptive (right fingertip) target with their unseen left fingertip
- Persistent shift in perceived location of both visual and proprioceptive targets after exposure to shifted visual feedback
- Visual shift aftereffect < Imposed shift  
⇒ Some component of adaptation at the motor level

Proprioceptive perceptual shift

## Existing Models

Maximum Likelihood-Based sensor recalibration [1, 7]

- Discrepancy between vision and proprioception eliminated by adjusting each estimate towards max. likelihood estimate (MLE)
  - Does not use knowledge of issued motor commands
  - No component of motor adaptation
- Can plausibly be combined with a distinct motor adaptation model to fully describe trial-to-trial behaviour
  - Independent sensor calibration and motor adaptation
  - Tacitly assumed in [7] to infer relative precision of vision and proprioception
- No direct experimental evidence to support independent sensor/motor adaptation

## Modelling Framework

### Model of a generic visuomotor adaptation experiment

Simplified model of a single reaching trial under experimentally controlled perturbations:

- Final hand position  $y_t$  depends on motor command  $u_t$ , motor disturbance  $r_t^u$  and motor noise  $\epsilon_t^u$

$$y_t = u_t + r_t^u + \epsilon_t^u; \quad \epsilon_t^u \sim N(0, \sigma_u^2)$$

–  $r_t^u$  controlled via manipulandum, inertial load

- Subjects' visual observation of hand position is noisy and shifted

$$v_t = y_t + r_t^v + \epsilon_t^v; \quad \epsilon_t^v \sim N(0, \sigma_v^2)$$

–  $r_t^v$  controlled via prisms, virtual reality apparatus

- Proprioceptive observation is also noisy and perturbed

$$p_t = y_t + r_t^p + \epsilon_t^p; \quad \epsilon_t^p \sim N(0, \sigma_p^2)$$

–  $r_t^p$  manipulated by vibration of muscles (less common)

- Equivalent assumptions are quite common in the motor adaptation literature, e.g. [7] (Vision/Proprioception model), [6] (Dynamics model)

## Bayesian Adaptation Model

### A unified approach to motor adaptation and sensor recalibration

Optimal joint inference of the three potential sources of systematic error.

- What the subject believes and observes:

- Subject maintains a statistical estimate of the total disturbance  $\mathbf{r}_t = (r_t^v, r_t^p, r_t^u)^T$
- Subject has internal model of how disturbances are liable to vary over time [3, 4]

$$\mathbf{r}_{t+1} = A\mathbf{r}_t + \xi_t; \quad \xi_t \sim N(0, Q) \quad (1)$$

- Current beliefs about disturbance represented as a multivariate Gaussian:

$$P(\mathbf{r}_t) \propto e^{-\frac{1}{2}(\mathbf{r}_t - \hat{\mathbf{r}}_t)^T P_t^{-1} (\mathbf{r}_t - \hat{\mathbf{r}}_t)} \quad \begin{array}{l} - \hat{\mathbf{r}}_t = \text{Estimate after trial } t \\ - P_t = \text{Uncertainty} \end{array}$$

- Motor commands chosen on each trial according to most likely set of disturbances

### Optimal inference of the disturbances

Subject infers posterior estimate of the disturbances given new observations from each trial, motor commands issued, and prior beliefs (posterior from previous trial)

- Equivalent to a Kalman filter with latent state  $\mathbf{r}_t$ , state transition model (1) and observation model:

$$\begin{pmatrix} v_t - u_t \\ p_t - u_t \end{pmatrix} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix} \begin{pmatrix} r_t^v + \epsilon_t^v \\ r_t^p + \epsilon_t^p \\ r_t^u + \epsilon_t^u \end{pmatrix} \quad \text{or} \quad \mathbf{z}_t = H(\mathbf{r}_t + \epsilon_t)$$

- Observation noise:  $H\epsilon_t \sim N(0, R); \quad R = \begin{pmatrix} \sigma_v^2 + \sigma_u^2 & \sigma_u^2 \\ \sigma_u^2 & \sigma_p^2 + \sigma_u^2 \end{pmatrix}$

- Standard Kalman filter updates yield optimal estimate  $\hat{\mathbf{r}}_{t|t-1}, P_{t|t-1}$  at the start of each new trial. This dictates choice of motor command  $u_t$  on each trial and therefore the hand position  $y_t$  predicted by the model.

## MLE-based Model Details

Although no explicit model has previously been proposed, existing models of motor adaptation and sensor recalibration can be plausibly combined.

- Max. Likelihood estimation of hand position (MLE) from vision and proprioception

$$\hat{y}_t = \frac{\sigma_p^2}{\sigma_v^2 + \sigma_p^2}(v_t - \hat{r}_t^v) + \frac{\sigma_v^2}{\sigma_v^2 + \sigma_p^2}(p_t - \hat{r}_t^p)$$

- Uni-modal motor adaptation using hand position MLE

$$\hat{r}_{t+1}^u = \hat{r}_t^u + \beta(u_t + \hat{r}_t^u - \hat{y}_t)$$

- Sensor recalibration eliminates sensory discrepancy by adjusting each estimate towards MLE [1]

$$\begin{array}{l} \hat{r}_{t+1}^v = \hat{r}_t^v + \gamma \sigma_p^2 [(v_t - \hat{r}_t^v) - (p_t - \hat{r}_t^p)] \\ \hat{r}_{t+1}^p = \hat{r}_t^p + \gamma \sigma_v^2 [(p_t - \hat{r}_t^p) - (v_t - \hat{r}_t^v)] \end{array}$$

## Results

- Both models fitted to data using Matlab (lsqnonlin)
- Data taken from [4]:
  - Reaching to 8 targets around a circle
  - Data represents average over cycle of 8 targets
  - Day 1 - Adaptation to 30° rotation of visual feedback
  - Day 2 - Retesting on same 30° rotation

Original data

- Overnight forgetting model:  $\hat{\mathbf{r}}_T = B\hat{\mathbf{r}}_{T-1}$  ( $T$  = first trial of new day)

- Free parameters:

$$\begin{array}{l} \text{– Bayesian: } \sigma_v^2, \sigma_p^2, \sigma_u^2, \quad A = \begin{pmatrix} a & \dots \\ \dots & a \end{pmatrix}, \quad B = \begin{pmatrix} b & \dots \\ \dots & b \end{pmatrix}, \quad Q = \begin{pmatrix} q_v & \dots \\ \dots & q_p \\ \dots & \dots & q_u \end{pmatrix} \\ \text{– MLE-based: } \sigma_v^2, \sigma_p^2, \sigma_u^2, \beta, \gamma, b \end{array}$$

## MLE-based Model

Performance (error in  $y_t$ )

Estimated Disturbances ( $\hat{\mathbf{r}}_t$ )

Fitted Parameters			
$\sigma_v^2$	0.0845	$q_v$	0.0219
$\sigma_p^2$	0.0189	$q_p$	0.0144
$\sigma_u^2$	1.6380	$q_u$	0.0050
$a$	0.9961	$b$	0.7000

## Bayesian Model

Fitted Parameters			
$\sigma_v^2$	0.2789	$\beta$	0.1187
$\sigma_p^2$	0.7320	$\gamma$	0.0052
$\sigma_u^2$	0.5050	$b$	0.6534

## Conclusions

- Unified approach to motor adaptation and sensor recalibration
- Able to account for perceptual aftereffects of adaptation to shifted visual feedback
- Multiple modelled disturbances leads to richer adaptation dynamics
  - Good agreement with experimental data
  - Bayesian model provides superior fit compared to MLE-based model

## Future Work

- Experimental testing of model predictions
  - Can changes in dynamics elicit perceptual aftereffects in the same way that shifted visual feedback can?
- Improved parameter estimation (EM-based)
- Extension to nonlinear disturbances/adaptation
  - Different generalization patterns for kinematic vs dynamic disturbances
